It remains to deal with the major bond. At room temperature this bond, together with the total pressure, more than balances the reversion force. But since the minor bond has been disposed of by lowering the temperature, and with it the pressure, there is good reason to believe that with a further lowering of temperature a critical point would ultimately be reached at which the greatly reduced pressure, plus the force of the major bond, would be outweighed by the reversion force; at that point, possibly a long way down the scale of temperature, all the iron caught in the major bond—which is as much as to say all the iron remaining in the non-magnetic state—would revert to the magnetic condition. This final transformation having taken place, all the solvent iron would be in the magnetic state and so far as magnetisn is concerned the steel would have assumed the normal or all-Alpha condition. Whether this method of overcoming the major bond by low temperature is practicable depends on whether the critical temperature is within easy reach. The discovery of the harmful effect of ultraheating on magnet steel being of recent date, the author has had no opportunity to determine the whereabouts of the critical point. There should not be much difficulty in finding it, since liquid air boiling at 182 degrees C. below zero is available for experiment.

The alternative to overpowering the ultraheating bonds by lowering the temperature is to get rid of the harmful effect of ultraheating by actually breaking the

bonds. This can be done and by good fortune it only needs heat treatment of a simple kind. In one form the method is already in use by toolmakers as a means of softening high-speed tool steel, though whether the toolmaker clearly understands what is happening to the steel is open to doubt. A hint of what is needed to break the major and minor bonds is to be found in Fig. 41, where the curve which gives the rate of growth of the magnetic intensity clearly shows that non-magnetic iron began to be converted into Alpha iron at about the temperature where the magnetic change would have been in progress if the steel had been in the normal state. This slight reversion to the magnetic condition suggests the possibility that the ultraheating bonds began to break up within that region of temperature, but that something checked the progress of reaction. However, the diagram conveys no more than a hint, and to obtain further light we must once more turn to the magnetic 54 minutes being occupied in traversing the 50 degrees. At 700° C. the cooling speed was restored to the normal rate of 29 degrees a minute.

Looking at curve E, it will be noticed that when the steel cooled down at the high speed of 100 degrees a minute, the final percentage intensity of magnetization at 50° C., practically room temperature, was only 87, showing that 13 per cent of the solvent iron was still under the restraint of the major bond. But curve F shows that at the slower cooling speed of 29 degrees a minute the final percentage intensity rose to 94, indicating that the slower cooling had resulted in the release of 7 per cent of solvent iron from the major bond. From the course taken by the curve below 750 as far as 600° C., it seems that the release took place while the steel was traversing that region of temperature, and if the steel had cooled still more slowly the additional time within that region would have

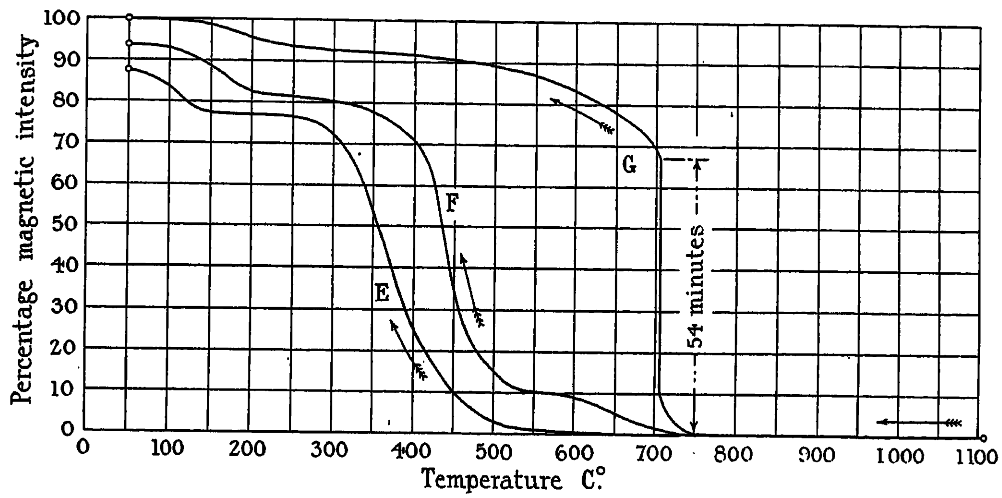

FIG. 44.—Curves showing recovery of magnetism in tungsten magnet steel when cooling from a temperature just above 1 100° C. at different speeds. E at 100 degrees a minute; F at 29 degrees a minute; G at 1 degree a minute. [Honda.]

recovery curves recorded by Honda and Murakami, choosing a set of curves relating to tungsten steel not too widely different from ordinary tungsten magnet steel. Fig. 44 is reproduced from a diagram containing three recovery curves obtained from a specimen of steel containing 7·9 per cent of tungsten and 0·63 per cent of carbon. Each curve is plotted from observations made while the specimen was cooling down from 1 100° C. This temperature being above the ultraheating boundary, the specimen was of course in an ultraheated condition, but it is unlikely that the ultraheated state would be fully developed at a temperature so little above the critical point at 1 073° C. The marked differences between the three curves arise from the widely different rates at which the steel was cooled. In curve E the cooling speed between 700° and 350° C. was 100 degrees a minute. In curve F the same range of temperature was traversed at 29 degrees a minute. In curve G the rate of cooling was intentionally checked at 750° C., and from that point down to 700° C. the cooling was reduced to something like 1 degree a minute, resulted, no doubt, in the release of a greater quantity of solvent iron from the major bond.

That the major bond slowly comes undone just below 750° C., and that the release of the whole of the iron caught in that bond is only a question of time, is clearly shown in curve G. In the course of 54 minutes, the temperature being nearly constant at about 700° C. for most of the time, all the solvent iron was released from the bondage set up by ultraheating, and the recovery of magnetism was complete. To state the fact in another way, the breaking of the ultraheating bonds, which is evidently in progress at about 700° C., goes on so slowly that it needed 54 minutes to complete the undoing and remove the effects of ultraheating. We could hardly have a better example, for these three curves demonstrate all the essential facts. Cool the steel quickly, and the major bond survives intact at room temperature for want of time to come undone while the temperature was traversing the breaking-up region. But if there is enough time within that region for the complete breaking up of the ultraheating bonds,

the whole of the solvent iron will be released from bondage. Since the breaking-up region is just below the temperature zone of the magnetic change in normal steel, the release of non-magnetic iron from either of the ultraheating bonds is, of course, followed immediately by its reversion to the magnetic or Alpha form.

It is clear that whatever heat treatment it may be convenient to use for the purpose, the actual curing of the ultraheated steel will take place only while the temperature is within the region where the ultraheating bonds break up. Assuming that a piece of ultraheated steel has already cooled down to room temperature, the minor bond will have been overcome. To break the major bond, the steel may first be heated to some temperature above the breaking-up region (taking care not to approach the ultraheating boundary) and then immediately allowed to cool down through the breaking-up region. This method is illustrated by curves C and D in Fig. 42. The ultraheated steel having been heated to 935° C. and then cooled down to room temperature, the curves show that about 10 per cent of the solvent iron was released from the major bond during the passage through the breaking-up region, which extends from 750 down to about 600° C. Heating the steel to so high a temperature as 900° C. is, however, quite unnecessary. It would have answered the purpose equally well to raise the temperature to the upper boundary of the breaking-up region (about 750° C. in the case of tungsten magnet steel), and then to allow the steel to cool down slowly.

The severing of bonds, the magnetic change and the consequent passage of carbide from solution to crystal, involves the liberation of a good deal of energy as heat, and unless this heat is removed the temperature of the steel rises and the whole process stops. To keep the process going, therefore, it is necessary that the temperature of the walls of the furnace should be somewhat lower than the temperature of the steel, a condition which involves a falling temperature. With but little difference of temperature between steel and furnace wall the whole process of change goes on extremely slowly, but there is ample time for the complete breaking-up of the ultraheating bonds before the temperature of the steel falls below the breaking-up region. This was the condition under which curve G in Fig. 44 was obtained, and the very slow cooling resulted in the release of 13 per cent of the solvent iron from the major bond. If the steel had been fully ultraheated there would have been rather more than 16 per cent of solvent iron caught in the major bond, and a good deal more time would have been needed to release it. On the other hand, if a greater temperature difference is established between the steel and the furnace wall in order to accelerate the process of change, the temperature of the steel falls more quickly and may pass below the breaking-up region before the breaking up of the major bond has been completed. This was the state of things when curve D in Fig. 42 was obtained, and the cooling, which went on at the rate of about 26 degrees a minute resulted in the release of only 10 per cent of the solvent iron from the major bond. These two examples make it clear that the quantity of solvent iron released from the major bond, as the temperature of the steel falls through the breaking-up region, is largely governed by the cooling speed.

The most generally convenient way of curing ultraheated steel is to heat it to some temperature just above the breaking-up region and then let it cool down through that region at the rate of about 15 degrees a minute. At this speed about 12 per cent of solvent iron will be released from the major bond, and to effect the complete cure of fully ultraheated tungsten magnet steel a repetition of the temperature cycle would be necessary. The only practicable alternative to treatment by two heat cycles is to reduce the cooling speed to such an extent that an hour or more is occupied in lowering the temperature from 750 to 600° C.

Ultraheated cobalt magnet steel has yet to be investigated. Judging from a few scattered observations made in the course of other work, ultraheating has a much greater effect on cobalt steel than it has on tungsten steel. With two solvents, iron and cobalt, mutually soluble in each other, and at least three kinds of solute molecule, including a chromium carbide, it seems probable that more than two kinds of bond would be brought into existence by ultraheating. One of them is likely to prove troublesome, for long before the discovery of cobalt magnet steel there was reason to suspect that the presence of chromium in steel creates an ultraheating bond of an extremely persistent kind.

So far as the curing of ultraheated tungsten magnet steel is concerned we are now out of the wood. Since the phenomena of ultraheating are only to be found in steels which, in addition to carbon, contain tungsten or some element of similar character, it is obvious that under certain conditions solute molecules which contain foreign elements of that kind acquire the power of holding iron molecules in the non-magnetic state. But although it is possible to identify certain types of solute molecule endowed with the power of holding non-magnetic iron molecules in some kind of bondage, the nature of the force exerted, and how it is brought into action by ultraheating are shrouded in mystery.

Discussion before The Institution, 19 March, 1925.

Mr. Ll. B. Atkinson: The present paper is a continuation of a previous paper in which the author dealt with two questions, different but, of course, connected. He dealt with the theory of permanent magnetism and he dealt up to a point with the practical construction of magnets, that is to say, the predetermination of a magnet for a given task. In that paper he took steel, shall we say, in the abstract—steel as he found it—and showed us how with that and its properties, for which he gave a theory, we could predetermine the magnets by methods which he then laid down. The present paper carries us forward a further stage. The author gives a theory not only of the source of the magnetization of steel, but also of all the various defects and faults

which are found in magnet steel. In the previous paper the author put forward his theory of permanent magnets. At that time we were looking on magnetism as something produced in iron by a coil giving a magnetomotive force acting on a medium which had a reluctance or permeance varying with the flux it was carrying, and so a flux was produced. It was the image of an electromotive force acting on a resistance which itself depended on the current being carried. The author took us away from that idea altogether to the idea that the exciting coil was only, as it were, a trigger which set off, by orienting the molecules, something else which was inherent in the iron. Every molecule had a fixed magnetomotive force which acted always on a medium—the ether—of a constant permeance. That was a revolution in thought. It was one, to me at least, not easy at the moment to accept, and I took exception to one or two points. An argument which I raised was the question of the orientation of these molecules, having in view the fact, as it appeared to me, that this permanency or constancy of magnetomotive force was impossible in view of the fact that unless an electromotive force is applied to a circuit of perfect conductivity (which we may assume the electron orbit to be) the electro-kinetic momentum, that is the flux, through that orbit will remain constant. In the author's reply he admitted that there is not absolute constancy of the magnetomotive force, yet pointed out that with reasonable dimensions of the electron orbit and the distances of the molecules, the detectable difference is so small, running into one part in many millions, that for all practical purposes, and for all theoretical purposes with which we are concerned, there is that constant magnetomotive force. No one, I think, can doubt that this paper, with the preceding one, has made the ground perfectly plain as to the procedure necessary to make carbon, tungsten and cobalt magnets with certainty. No one, I think, can doubt after studying this paper that the Ampère-Weber conception of the molecule and the Ewing explanation of the magnetization of iron are in broad principle correct. That the permanency of the magnetic state is due to variform spacing of the molecules is at least a reasonable hypothesis, though I think there are other possible ones. The author suggests that the alteration of iron from the Alpha to the Beta state takes place by the iron molecule being composed of two atoms, that is, containing two electronic orbits, which normally and in a stable condition are lying parallel to one another. He suggests that by some means those two orbits are oriented so that they face one another. The electrons are then revolving in opposite directions and annul one another so far as any magnetomotive force is concerned. He points out that under those conditions those two electronic orbits are not in a stable position. They must be put there by something and held there by something; and he suggests that that something is the kinetic pressure arising from those movements of the iron particles which we call heat, and the kinetic pressure arising from what we call solution pressure. I find it very difficult to form any sort of mental image of how an orientation which is a directive process can be brought about by kinetic pressures which are essentially non-directive. I think that the author is on much safer ground in the earlier part of his paper when he points out that these allotropic changes are equivalent to the production of new elements. If we imagine, for instance, that at a temperature of about 800° C. iron turns into copper we do not need to say to ourselves that the copper has this sudden change of the orbits so that they are going to turn into an unstable position. It appears to me that if this latter were the explanation, then the temperature at which the change takes place could be varied by the strength of the magnetic field in which the whole iron was placed. We know that in the gaseous state—and, after all, most of what we know about electron orbits is when they are in the gaseous state—the electrons revolve in a variety of orbits. We know also that when they change those orbits they do not do it gradually but with a sudden jump from one orbit to another. Whether that happens in the solid state or not I do not know, but it does appear to me that some such change of a very sudden nature is better able to account for this change which takes place comparatively suddenly at a temperature of about 760° C. These questions, as the author points out, will presently be resolved. Such theories are useful as a guide to further experiment. They do not affect the fact that the author has now placed in our hands a complete knowledge of the permanent magnet as an electromagnetic entity.

Mr. E. A. Watson: The author refers throughout the paper to the carbide being in solution in the Alpha iron, although in one paragraph he states that it is the pattern of a solution which counts. I cannot quite agree with him that the carbide is really in solution. It is in a very similar position, and it is rather difficult to say really when the carbide is in solution and when it is not. A very rough and crude analogy would be to consider a vast crowd of people into which a comparatively small number of strangers of another nationality are introduced. In the beginning the crowd has a sort of friendly feeling for the strangers and gathers them into its midst. Each little group of the crowd takes a stranger and makes friends with him. Then, all of a sudden, war is declared and each little group ejects its stranger from it, but it takes some time for the strangers to gather together to form their own little groups. I look upon hardened steel as being a crowd in which the strangers have been ejected from the groups and have not crystallized to form their own group. Although the difference between the author's conception and my own is really a very small one, it has its importance. If the carbides are really in solution, and the hardened steel is heated so as to give a chance for the recrystallization of the carbide molecules, there should surely be a heat emission corresponding to that absorbed when the carbide goes into solution. I have made one or two experiments on these lines, on cobalt steel, and so far have been unable to trace any sign of the heat emission, though I admit the experiments were only rough ones, and the effect, particularly if spread over a wide range of temperature, may have been overlooked. Possibly the author may be able to throw more light on this subject. After all, it is not a very important point and is chiefly a distinction in

words only. We are all agreed that the carbide is in practically molecular subdivision in the steel. Another point on which I must disagree with the author is on the question of chrome steel, which he dismisses rather briefly. In fact he refers to the chromium as helping to retain Gamma iron in hardened steel, and as diminishing the magnetism in the finished magnet. I will grant that chrome steels are not quite as good as tungsten steels, but I do not think that there is very much difference between the two. It is natural that the author, being a master in the art of tungsten steels, possibly might not give credit to the others, but it is certainly significant that chrome steel should be used so largely in other countries. In the United States one hardly ever sees the tungsten steel magnet; all the magnets are of chrome steel, and the figures given to me last summer in the United States by a good many users of chrome steel magnets showed that they were getting energy values very little inferior to those obtained with tungsten steel magnets in this country, and certainly the remanence values were very little less than the figures given by the author. At the same time chrome steels are considerably cheaper than tungsten steels, and I believe it is true that on a basis of cost only the chrome steel magnets show an advantage. Further, the chrome steel magnet is said to give less trouble in hardening than the tungsten steel magnet, although on this point I have no first-hand experience. It is, I think, a significant fact that the Ford Company should employ chrome steel magnets in the flywheel generator fitted to the Ford car. I believe it is true that the choice of materials on this car is invariably made with great care, with a view to the maximum ultimate economy and efficiency. But if the author has not done justice to the chrome steels, I am afraid he must be said to have failed to make a fair statement of the case of the cobalt steels. Unfortunately, he does not give the composition of the cobalt steel (which he quotes in Table 9) as giving a value of 30 300 ergs per cm^3 of steel, but the value of 30 300 is by no means the best that can be obtained. With a 35 per cent alloy, values of $(BH)_{max.} = 1\,000\,000$, or say $e = 40\,000$, are by no means uncommon, and I think that any maker would guarantee 800 000, or $e = 32\,000$, for this steel. The author quotes a price of 7s. 6d. per lb. for this steel. Whilst this price is frequently asked, it is really by no means one that is comparable with the other prices given. If we assume that the basis material cost of the steel, without the cobalt, is 15d. per lb., and the cobalt itself costs 10s. per lb. (the present price in large quantities), we obtain a price of $0{\cdot}65 \times 15 + 0{\cdot}35 \times 120 = 9{\cdot}75 + 42$, or 4s. 3¾d. per lb. I am not, of course, suggesting that the author can buy 35 per cent cobalt steel at this figure, as the steelmaker must allow something on the cobalt which he handles, but I am quite sure that 7s. 6d. is an unduly high figure to take. Further, the 35 per cent steel is not, in general, the most economical composition, i.e. it does not give the maximum value of $(BH)_{max.}$ for a given cost, so that a still better comparison might be made, if necessary. Another point which has apparently been overlooked, is that the cobalt steel magnet, being smaller in dimensions and containing less material, is cheaper to handle and to harden than the more bulky tungsten steel magnets which perform the same function. I quite agree with the author that in the general case, where a given magnetic flux has to be provided, and where no limitations of space are imposed, the cobalt steel magnet is not the most economical way of providing the flux, but I do not agree that there is the disparity he suggests. Perhaps one of the most important and novel points raised in the paper is the decay of potency in the hardened magnet. It is well known to magnet makers that there is a considerable falling off during the first day after hardening. It is also a well-known fact to the ordinary magnet maker that the remanence of the steel rises very considerably during the first day after hardening. The author makes no reference to any increase in the remanence, and again my own experience on cobalt steels is that the increase in remanence during the first day or so balances the decrease in the coercive force, and the result is that the value of $(BH)_{max.}$ remains constant, or even rises. A question that arises in this connection is whether this decay in potency may not depend on the type of molecule which gives the potency to the steel; in other words, will the decay in potency be the same when a comparatively slow-moving molecule is employed as when a very mobile molecule is employed? I am thinking now of a comparison between an air-hardening steel and the ordinary water-hardening steel. The author's figures are for water-hardening steels, and as a matter of interest I have taken some figures on an air-hardening steel. Of course, this ageing effect occupies a series of years, so to get comparable results I boiled a magnet in water and took a comparison of the ageing in boiling water for the air-hardening steel as compared with the ageing given in the paper for the water-hardening steel, and I found that whereas in the author's case the tungsten steel lost about 5½ per cent of its potency in seven hours' boiling, the air-hardening steel lost only 3½ per cent in 48 hours, which seems to indicate that possibly the nature of the potency-giving molecule may have quite an appreciable effect upon the decay in potency. I think I might say that if it were for one clearly proved statement alone the paper deserves a place in posterity, and that is the proof that Beta iron is not the cause of hardness of a properly hardened steel. Many metallurgists, who should know better, have made this statement—let us hope that hereafter it will be made no more.

(*Communicated*): The author's explanation of the spoiling of tungsten steel would appear to be a very reasonable one. In the case of cobalt steels there is little doubt that a similar condition of affairs holds, particularly in view of the tendency of cobalt to promote the separation of graphite, but it would appear possible that there is another cause of the spoiling of steel, and that is in the tendency of the carbides to coalesce during annealing. Certainly spoiling can occur in cobalt steels through annealing at comparatively low temperatures, and this spoiling can be remedied by heating the steel to a comparatively high temperature. The temperature, however, is considerably less than that corresponding to the formation of Delta iron. A temperature of 1 150° C. seems to be quite effective, and

unless in these cobalt steels the Gamma-Delta transformation occurs at a lower temperature than in a carbon steel, the explanation given by the author does not hold. Much more research work is really required, however, before it is safe to dogmatize as to what does, or does not, happen in a steel of this nature. The author's reference to cobalt as a counteracting agent for the effect of chromium in reducing the amount of Alpha iron, strikes me as a little strange. True cobalt does simulate the effect of an increased proportion of Alpha iron, but that is really another story. We have all heard of the cobalt-iron compound corresponding to the formula Fe_2Co, which has a saturation density some 15 per cent greater than that of pure iron, and we should naturally expect that, other things being equal, the substitution of iron by cobalt would raise both saturation density and remanence, or, as the author would put it, would increase the average magnetomotive force of the current rings. This hardly seems to be quite the same as counteracting the influence of chromium. In fact the properties of a series of steels with constant chromium and increasing cobalt furnish no such evidence and show no increase in the apparent proportion of Alpha iron, which could not be accounted for by the presence of Fe_2Co. Right through the paper there appears to run the tacit assumption that in a properly hardened tungsten steel magnet which has not been ultraheated the whole of the iron (apart from that combined with the carbon as Fe_3C) is in the Alpha or magnetizable form. It is a very simple conception and one which makes the structure of a properly hardened magnet extremely simple, but I think that experimental evidence casts a little doubt on this, for if we take the composition of tungsten steel given in Table 11 and, after making allowance for that portion of the iron associated with the carbide as Fe_3C, calculate the theoretical value of the saturation density, we obtain a figure of 18 900 (taking pure Alpha iron as 21 500), a value which I think I am safe in saying is never attained nor even closely approached by a hardened tungsten steel of this composition. In fact, if we use the so-called reluctivity relation to calculate the value of the saturation density from the *BH* curve, we usually obtain a value of between 13 000 and 14 000 only, as the saturation density of the iron associated with the carbide molecules. It would, in fact, appear possible that every permanent magnet contains, in addition to the Alpha iron properly associated with the carbide and forming the magnetic structure, a certain amount both of unassociated Alpha iron and also of iron in the non-magnetic condition. As to whether such a state of affairs is purely accidental and due to defect in treatment or material, or whether it is a natural necessity, I think it is impossible to say at the present juncture.

Sir Herbert Jackson: One welcomes any work which thows light upon the nature of magnetism and which shows what increased uses there are for the phenomena of magnetism. In the course of some investigations into the properties of certain suspension parts of galvanometers it has come to this—that in the desire to know what is giving permanent magnetism to certain parts we should like to find out the condition of the iron. Modern methods of chemistry are very subtle, but we came definitely to a point when it was impossible to throw any further light on the subject by chemical study. After prolonged survey, in dealing with permanent magnetism in these materials, it seemed quite clear—and I need not labour this point—that magnetism had carried us a long way further in determining the possibility of whether iron exists in the form of ferroso ferric oxide or in the form of steel. That, I think I may say with certainty, would be entirely outside anything that could be hoped for from work done on a chemical basis. The actual quantities dealt with were almost so small as to be beyond our powers to deal with, but they were in materials from which they could not be separated without destroying the materials and changing their character.

Mr. J. F. Kayser: I do not agree with many of the metallurgical statements made by the author. In the first place I think that he has not paid sufficient attention to the line of research opened up by Mr. Watson. The author in referring to the microscope practically says that it will not magnify enough—that in order to get any indication of magnetic properties by what one may call visual observation, one must be able to see atoms. I think, however, that that is not the case. The steels or the alloys of which magnets are made consist of a conglomeration of crystals and intermetallic compounds, and the forms of those crystals depend upon the arrangement of the molecules in the lattice structure. By observing the type of crystal and its behaviour we can form a very good indication of what is happening within the molecule itself. I think it would be far better not to go to the ultra-microscope or to X-rays, but to examine the steel under, say, 8 or 10 diameters. A good tungsten magnet steel if observed at a magnification of 8 000 diameters shows very little indeed, but if it is etched to show the macro-structure a very great deal can be learned. The author states that Alpha iron maintains in solution naturally—that is without being heated to a high temperature and then rapidly cooled—approximately 0·24 per cent of carbon. I suggest that the figure should be 0·024. It is quite possible to see the carbon existing in a steel containing 0·1 per cent of carbon in the form of Fe_3C. To pass now to the more magnetic side of the question, let us take the spoiling of steel. In the first place it is most difficult to roll the more expensive varieties of steel without hovering for a very long time in the danger zone, and that is one of the reasons why we must spoil steel. Some of us do know how to recover it, but when we suggest the recovery process electrical engineers are up in arms. It is now three years since I suggested a triple heat treatment for magnet steels, and that treatment has been followed to a very great extent upon cobalt steels. In that treatment the steel is first given high coercive force antecedents by being heated to a temperature somewhat higher than 1 150° C. That produces an ultraheated condition, which must be removed by a low-temperature treatment in the vicinity of 750° C. After those two treatments the normal hardening is carried on. My experience with cast magnets does not quite coincide with that of the author. During the last month I have probably

cast something like half a million magnets, and small magnets confirm absolutely what he says. The remanence is quite high and the coercive force is in fact higher than that of a similar composition of forged material; but with larger magnets which maintain something like 80 000 lines a very great falling off in remanence is noticed.

(*Communicated*): I am afraid that, in his endeavours to air the metallurgical aspect of permanent magnets, the author has based explanations of carefully observed magnetic results upon many erroneous statements to such an extent as to detract very greatly from his theories. Referring to the rate of the passage of solid molecules from solution to crystal, he states that, even when red-hot, the process, in the case of solid steel, is found to occupy several minutes. Such is not the case. At the change point iron carbide (Fe_3C) falls from solution exceeding rapidly—in fact, according to most observers, instantaneously—when once the temperature and rate of fall of temperature are favourable for its separation. Later in the paper the author's use of the word "alloy" is very vague and indefinite. Referring to the nickel-iron series on page 747, he states "and from this it was clear that the metals formed an alloy." It is well known that nickel and iron form an infinite number of alloys with one another. Whilst his explanation of the spoiling effect of soaking fits a few of the theoretical deductions which he has quoted, it nevertheless does not fit in with the facts shown by microscopic analysis, and if he examines a series of spoiled and unspoiled magnet steels I think he will finally agree that soaking brings about a visible association of free carbides into, comparatively speaking, large globules, which do not go into solution when the steel is subsequently hardened at a temperature sufficiently low to retain the greater part of the material in what the author would probably call the non-ultraheated condition. My experiments tend to show that the temperature necessary to restore spoiled tungsten magnet steel is considerably lower than that stated by the author, and I have obtained complete recovery at between 1 150° C. and 1 200° C. This high-temperature recovery process leaves the steel in the ultraheated condition, a fact which the author does not seem to have observed. In order to remove that condition it is necessary to adopt an intermediate treatment before carrying out the final hardening. On behalf of a considerable number of Sheffield steel manufacturers I can assure the author that the manufacture of permanent magnets, and of the steel from which they are made, does not proceed on mediæval lines. Whilst the bulk of the best-quality magnet steel made in this country is manufactured by means of the crucible steel process, a very large tonnage is also manufactured in electric furnaces. Melting large quantities in one furnace often leads, however, to the very defect against which the author levels most of his complaints, i.e. spoiling. This is brought about by the fact that it is extremely difficult to cast large masses of steel into small ingots, and when large ingots are produced they must necessarily be maintained at a temperature within the danger zone for a much longer period than smaller ingots. The figures given in Table 9 are very misleading. A 35 per cent cobalt steel gives a maximum available energy considerably in excess of the figure of 30 300 ergs per cm^3 given by the author, and for the past three years it has been procurable in unlimited quantities at a price of about 70d. per lb., i.e. more than 20 per cent cheaper than the figure given in the paper. It is difficult to discuss the results given under Section (16), "The Gradual Decay of Hardened Steel," in so far as they relate to cobalt steel magnets, as the composition of the cobalt steel is not given and, from the demagnetization loops given in Fig. 23, I venture to suggest that either the cobalt steel referred to was of an unusual composition or was not treated to give the highest possible maximum available energy. During the past six years several hundreds of thousands of magnets have been manufactured under my control, and every one has been tested before leaving the works. Whenever possible, the value of $(BH)_{max.}$ has been determined, whilst, in other cases, the flux on open circuit has been checked. On looking through my figures I find that in every case the maximum available energy increases considerably during the first 24 hours after hardening; the coercive force, it is true, falls off somewhat, but the remanence, on the other hand, frequently increases by 300 to 500 lines per $cm.^2$ I have also a series of round straight-bar magnets, which are kept in the laboratory for the use of unskilled testers who test current products, and some three years ago I was very much troubled by being unable to bring up a large batch of magnets to the figures maintained by the standards, but found that during the first 24 hours after hardening there was a very considerable increase, and that after a few weeks they were well up to the figures given by the original standards. In both this and his previous paper the author has avoided any reference to the serious demagnetization brought about by stroking a permanent magnet with a piece of soft iron. It is interesting to note that whilst after stroking a magnet on one side and in one direction for, say, 20 times a state of equilibrium is brought about, the same magnet can be further reduced by stroking it on another side. Another interesting fact is that the demagnetization due to stroking can be very largely eliminated by having a sufficiently thick layer of paint on the magnet, thus preventing absolute contact between the magnet and the soft iron. I should be very glad to know whether the author has any information in his possession enabling him to give a magneto-mathematical explanation of this phenomenon.

Mr. A. Brookes: I am not in agreement with the author's statement that microscopical examination is of little use. Admittedly, in a hardened magnet steel, the higher the magnetic characteristics the more homogeneous the structure, i.e. the less to be seen, but this of itself may be a useful guide. The value of the microscope is, however, in the examination of the steel *prior* to working up into magnets and heat-treating; that is, in the bar form as received from the suppliers. The microscopical examination in this stage does not appear to have been seriously studied by the author or by other investigators. From my investigations into the question of carbon tungsten steel, which the author's work has confirmed, the great secret lies in the perfection of solution. In my opinion, speaking from the industrial

research standpoint of the user of magnet steel, the study may be restricted to a considerable extent to that of the steel prior to hardening. The best heat treatment, a close estimation of which can be determined from the chemical and metallurgical analyses, is then determined experimentally to give the best magnetic characteristics. Until better light is thrown on to the state in the hardened condition, microscopic investigation may be left to the pure research of the metallurgist. A closer study of the theories of solution should provide a definite clue to magnetic properties. The question of the spoiling of magnet steel during the rolling process is an extremely important one. A spoiled magnet steel can readily be detected in the unhardened condition and the degree of spoiling can be determined to an extent that, knowing the general characteristics of the steel with which one is dealing, the drop in coercive force in the heat-treated condition can be estimated fairly closely from microscopical examination. A really good unspoiled tungsten magnet steel shows a uniform structure resembling a badly formed pearlite. Spoiling causes coalesced white areas to appear, and these do not go into solution completely on heating to the hardening temperature. These areas are easily distinguishable at 800–1 000 magnifications and are, I have presumed, a double carbide of iron and tungsten. Whatever they are, they appear to be the reason for the magnetic spoiling of the steel. It is hardly feasible that they can be free carbon, which the author suggests is the cause of the spoiling of magnet steel. There is no sign of these areas in the unetched condition, and the compound does not appear to lie along the grain boundaries. The author considers that the presence of both carbide of iron and carbide of tungsten increases the potency of the solution. Whilst believing this statement to be correct, the suggestion that the double carbide Fe_3CWC causes this increase in potency is, I think, quite erroneous. In fact, as previously stated, I believe that the formation of the double carbide is the reason of the spoliation of tungsten magnet steel. The white areas previously referred to are the important points in determining to what extent a steel is spoiled. That they contain carbon is shown by the decalescence point, which increases with a badly spoiled steel from a normal 780° C. to say 810° C., these temperatures depending, of course, upon the composition of the steel. In the high-temperature recovery process the white areas are dissolved and do not reappear on cooling, provided that the time of passing through the danger zone is reasonably short, such as would be given by drawing the steel from the furnace and allowing it to cool in the air. Two explanations have been advanced regarding the condition of the carbon and tungsten in magnet steels. That by the author is that they are present as Fe_3C and WC. Dr. Swinden suggested Fe_3C and iron tungstide. In support of his conclusion the author submits the coercive-force carbon-content curve of Fig. 9 that indicates a change in rise at 0·39 per cent C. This corresponds to the calculated percentage of carbon (6 per cent) necessary to combine with the amount of tungsten present. This particular curve is an important feature of the paper and is worthy of close consideration. From the inflexion of the curve between carbon contents 0·39 per cent and 0·7 per cent several important statements are derived later. In my opinion such statements, whether in themselves correct or not, are based on a fallacy. I contend that the inflexion in the curve is not correct, and tests over a number of years on steel from many different suppliers and of varying carbon content with approximately 6 per cent W give results which follow a smooth curve throughout from 0·35 per cent C upwards. A 0·55 per cent C, 6 per cent W magnet steel giving in the hardened condition a coercive force of less than 50 would unquestionably be considered as faulty steel. The figure should be approximately 60 as an average. In assuming that the change in the curve is accounted for by the additional potency due to the Fe_3C which is said to appear at this point, the author automatically suggests that previous to this point all the carbon is present as WC. The question of the carbide formations as derived from Fig. 9 requires much further investigation before such a basis can be accepted as authoritative. Following on the above the attempt to determine the degree of spoiling from the curve (Fig. 9) breaks down. I should certainly regard results in the neighbourhood of the inflexion as being due to spoiled steel or to faulty hardening. The explanation given of the abnormally high quenching temperature is also of interest in this connection. It is said that the *carbides* are all in solution at 790° C., and this is generally admitted to be correct. In any case the decalescence point is not appreciably altered from that of plain carbon steel. Therefore WC must be practically the same in dissolving temperature and effect on decalescence as FeC. The author explains that the necessity for an extra 60 to 70 degs. C. over a decalescence quench is to ensure soaking and hardness throughout. According to his theory all the potency-giving elements are in solution at 790° C., so that no advantage should be gained as regards improving the solution by raising the temperature beyond this point, or say beyond 800° C. It is well known, however, that it is necessary to raise the quenching temperature by 50–60 degs. C. above the decalescence point of the steel. The statement that the undisciplined mind demands this ample margin is, I think, an incorrect diagnosis. A very thin specimen giving little heat capacity, even under careful laboratory heat-treatment conditions, cannot be successfully hardened from 800° C., even with a time of soaking up to 20 minutes, if care be taken that this temperature is not exceeded at any time. Magnet steels are contrasted with tool steels, which are said to be hardened only on the outside edge. With tool steels of similar section to the magnet steels we generally use, they are certainly hard throughout. With large tools a softer core no doubt exists. Assuming that part of the tungsten is present as iron tungstide, I would offer this explanation: At 790° C. the iron carbide goes into solution completely, but the iron tungstide is not properly dissolved until a temperature of approximately 840° C. is reached. In this connection Fig. 33 may lead to confusion, unless it is fully appreciated that such quenching results are only given after the pre-heating treatment to 900° C. stated, or say a temperature above 840° C. There is no connection between the curves of Figs. 9 and 33, and the latter does not substantiate the theory in connection with the former. On the theory previously

mentioned regarding the formation of FeW and its solution at 840° C., Fig. 33 simply shows that such a solution may be maintained to as low as 750° C. The author states on page 744 that the tungsten content in a 0·72 per cent carbon steel may be varied from 5 per cent to 6·5 per cent without causing any material change in coercivity. I should like to confirm this and extend it over a period of carbon content from 0·55 per cent to 0·72. The result of such investigations as carried out several years ago came as a distinct surprise. With reference to the condemnation of chromium as a constituent of a tungsten-carbon magnet steel, it is essential in considering the effect of this element that the steel be in the unspoiled condition. Where the manufacturer has solved the problem of producing unspoiled steel, the benefit obtained is marked. With steels containing up to 0·5 per cent Cr with 0·6 C and 6 per cent tungsten, values of coercive force of 67, coupled with over 10 500 remanence may be obtained. With higher percentages of chromium the steel is gradually transferred into the oil hardening class, that is austensitic structure commences to be produced by water quench, with consequent degradation of magnetic properties. Other advantages are also given by the addition of chromium, which, however, are not dealt with by the author. At the same time the addition of chromium is not advisable in the hands of many steel manufacturers, as it is a trap for the unwary and a case where a little knowledge may be dangerous. I do not agree with the statement on page 770 that "it is unpracticable to forge or even to bend a piece of rolled magnet steel without heating it to a temperature within the danger zone." Magnet steel should never be heated beyond 750° C. or at any rate 800° C. during the forming processes. The question of decay of hardened magnet steel is extremely interesting, and is worthy of study. I made some investigations some time ago in respect to the decay of magnetic properties of hardened magnets when held at various temperatures from 100° C. to 400° C. for some hours. The magnets were remagnetized and ageing tests were carried out on them. Unfortunately the investigations were not completed, but they appeared to show that there was a very distinct difference in the decay between magnets which were carried through the temperature treatment in a magnetized state and those which were not magnetized. This point is being further investigated. As regards cracking when quenching between 800° and 900° C.—the usual range—it might be remarked that spoiled steel is naturally less liable to cracking than unspoiled. This is explained by the fact that all the potency-producing elements do not go into solution at the quenching temperature. The presence of chromium exceeding 0·5 per cent in an unspoiled water-hardened steel is an almost certain source of cracks, particularly with complicated shapes. As an example, a steel of composition 0·7 per cent C., 6 per cent W and 0·56 per cent Cr gave a high percentage of cracks with water hardening, but an interesting steel was one of composition 0·56 per cent C, 6 per cent W, and 0·65 per cent Cr, which according to the composition should have cracked freely, but could not be made to crack even with quenching in water from as high as 920° C. and hammering severely. The reason appeared to be, on investigation, that the presence of a proportionally large quantity of the double carbide reduced the sensitiveness so much that cracking did not occur. The author's experience that supplies of magnet steel are usually more or less spoiled will no doubt meet with general confirmation from many users of the material. It appears probable that makers are generally familiar with spoiling and spoiling conditions, but in fairness to them it should be acknowledged that the problem that confronts them is difficult in practice. The question of unspoiled steel is the most important problem before the magnet steel industry to-day, and is one which will have to be dealt with seriously if the trade is to be maintained. The trouble is principally in inconsistency of supplies; it can be stated practically that the technical requirements are solved, and that it only remains for a better handling of the steel, and more careful supervision in the rolling mills, particularly during the last stages of rolling. Is the author aware that certain suppliers have a rolling method which gives indications of being very different from the high-temperature rolling that appears to be largely practised? In my experience I have met with two classes of steel, amounting to several tons from various sources of supply. One class of steel, as supplied by the majority of magnet steel manufacturers, is usually more or less spoiled and the attendant evils of decarbonization and heavy scale are also evident. The other class usually has a very slight blue scale, no decarbonization, and is very rarely even slightly spoiled. In addition, the sulphur and phosphorus contents, more especially the former, are extremely small in the latter class of steel and are comparable with the highest grades of tool steel in this respect. I would suggest to the magnet steel manufacturers, therefore, that from the indications of hardnesses, magnetic tests and micro-structures that we have carried out on these steels, a serious study of the possibilities of low rolling temperatures with low-sulphur steels might be well repaid, and a more careful supervision of the rolling-mill conditions carried out. It would be more satisfactory to prevent the evils of spoiling than to attempt to cure them by the high-temperature recovery treatment, which is rather impracticable from a user's point of view. The investigations above referred to were carried out at the research laboratories of the British L.M. Ericsson Manufacturing Co., Ltd., Beeston, Nottingham.

Mr. A. Campbell: The author, after many years of patient and skilful investigation, has made a most valuable discovery which throws a flood of light on all the worrying inconsistencies that have so persistently beset all those who have made researches on magnet steel. He has found how good steel can be spoiled, and, better still, he has found how it can be cured. By this splendid achievement he has earned the heartiest thanks and congratulations of all who make or use permanent magnets.

Mr. L. E. Edwards (*communicated*): The comparisons which the author makes between certain cobalt-alloy magnet steels and tungsten magnet steels tend to give to the tungsten steels an undue proportion of merit. For example, from the results shown in Figs. 24 and 25 the conclusion arrived at by the author is that the

present rate of decay in the cobalt steel is $2\frac{1}{2}$ times greater than that in the tungsten steel. Now the *present* rate of decay cannot reasonably be taken to include the decay which took place during the first 12 months after hardening, and if that period is excluded it is found that between the 12th month and the 52nd month the decay rate in the cobalt steel is 0·9 unit per annum, and that in the tungsten steel is 0·75 unit per annum. The percentage potency decay works out at 0·54 per cent per annum for the cobalt steel, and 1·12 per cent per annum for the tungsten steel, showing the cobalt steel in a much more favourable light than the author's figures would suggest. Again, in Section (27) when making comparisons between experimental results obtained by Prof. Honda on cobalt steels and his own experiments on tungsten steels, the author himself states that numerical comparisons are not justified. The percentage reduction in flux density brought about by vibration on a permanent bar magnet does, it is believed, depend partly on the ratio of its length to virtual diameter and partly on the coercivity of the magnet steel. It would be manifestly unfair to compare the effect of shock on two magnets, one having a ratio (length: virtual dia.) of 10 to 1 and the other of 40 to 1. The percentage fall in flux density, assuming both magnets were made from exactly similar steels would be greater in the latter magnet than in the former. Prof. Honda's vibration tests were, it is understood, made on a cylindrical bar magnet 20 cm in length and 0·5 cm in diameter, giving a so-called dimension ratio of 40 to 1. The author would appear to feel that the potency decay taking place must tend gradually to diminish in rate; he is not, however, definite on this point. Judging from the curve given in Fig. 24 there would seem to be reasonable justification for the statement that the potency decay rate is gradually falling. To substantiate such a statement further the curve given in Fig. 34 may be cited as evidence, it being granted that ageing by time and by heat are to all intents identical in their effects on the internal structure of the steel. There is one point which must be well known to the author but which has not been raised, viz. the effect of "stroking" a permanent magnet with any magnetic substance. Taking any ordinary bar magnet in the magnetized condition it is found that vibration has an appreciable but a relatively small effect; whereas if the magnet be stroked with a piece of magnetic material there is an immediate and very large reduction in flux density. In this way, by stroking the whole of the exterior of any permanent magnet a very large reduction in flux density may be caused. It is found that the rate of loss in flux density caused by the stroking of a permanent magnet tends gradually to diminish and seems eventually to reach a point where stroking has no further effect. The author's explanation of the reasons for the demagnetizing effects of stroking would be instructive.

Mr. R. C. Woods (*communicated*): It would have been interesting had the author considered to a greater extent the electronic orbit theory of the magnetic atom instead of providing an ingenious and stimulating conception of the magnetic condition in a strictly limited sense, and to have taken more account of its significance as regards the (at present) non-magnetic substances. Admitting that our range of temperatures is limited, it seems strange, if the theory be true, that so very few substances exhibit magnetic properties in a state of unstable molecular equilibrium and none, so far as can be seen, have the electronic orbits fundamentally oriented in the stable condition. It would appear necessary to seek new methods of attack in order to follow up this line of thought to practical ends. The author states that the accuracy of the magnetic tests was considerably greater than that attained in the analysis of steel. I have considered an accuracy of 1 per cent as attainable for the usual ballistic tests with care and precision, and 2 per cent as excellent for a magnetometer, and if greater accuracy can be obtained by means of the apparatus used by the author a description of the instrument or method adopted would be helpful to those of us who are striving for greater accuracy in magnetic measurement. Judging solely by the difficulties experienced by the author in linking chemical composition accurately with the magnet specimen, it would appear that a short specimen is used, which would tend to render the observed values of coercive force open to much greater inaccuracies than if a longer specimen were employed. Has the author considered the production of the coercive-force carbon-content curve (Fig. 9) with the specimens quenched from a fixed temperature (say 60 degs. C.) above the decalescence point in each case. If the data are available, the production of such a curve would be well worth while, and I suggest that it would be of greater value in giving an indication of the available potency in the steel than the constant figure taken by the author when one considers that the decalescence range is approximately 100 deg. C. In this connection, too, within the commercial range of 6 per cent tungsten steel, the quench to give optimum coercive force should also give the maximum remanence obtainable within the hardening range of an unspoiled steel, thus giving the maximum available energy. Unless a strictly comparative basis be taken for the curve in question, the assumptions founded on that curve are open to doubt, and from my experience I do not consider that such an inflexion as that given in Fig. 9 would be obtained. With regard to the suggestion in Section (16) that softening may have been observed in carpenters' tools preserved over a period of 70 years and upwards, I have one or two tools, whose age is at least 80 years, of which the blades are still quite good, a Brinell test on a rabbet plane blade giving a hardness of 630. This has not, however, been in use for the past 50 years.

Mr. S. Evershed (*in reply*): The discussion, like the paper, has covered a wide field and I must confine my reply to a few of the more salient matters, resisting the temptation to wander in the metallurgical morass. So far as the generation of magnetism is concerned, Mr. Atkinson goes at once to the root of the matter. We were all taught to believe that just as electric current is set going by the electromotive force of a battery, so magnetic flux is generated by the magnetomotive force of an exciting coil. This idea carried with it the corollary that the quantity of flux depended on the reluctance of the flux path, in the same way that strength of current was governed by the resistance of the electric circuit. Just as different substances

differed in their electric conductivity, so different magnetic substances were supposed to differ in magnetic conductivity, or permeability as it was called. To Ampère, with the logical mind of the Frenchman, such a view would have seemed absurd and topsy-turvy. He only knew one kind of space and believed electric current to be the sole cause of magnetism in that space. He explained the great manifestation of magnetism in iron by assuming that every iron molecule embodied a permanent atomic electric current. Such was Ampère's hypothesis and now, a hundred years after his time, the atomic electric current he guessed at has been discovered in the planetary electrons of the atom. It is their powerful magnetomotive force, and not the relatively feeble force of the exciting coil, that creates the enormous flux in a magnetic circuit of iron or steel. To this point the astonishing discoveries of J. J. Thomson, Rutherford and others have brought us and we must adapt our ideas accordingly. What magnetism is, no one knows. We can only think of it as a peculiar condition created in space by the motion of electricity. The moving electricity may be a single electron rushing round its orbit in an atom of hydrogen, or the 26 planetary electrons of the iron atom, or the current generated in a coil by a battery. In every case the result is magnetism, and the space on which the moving electricity acts is the one universal medium. Knowing this, anyone who still finds it helpful to do so may write $B/H = \mu$ to express the numerical ratio of the flux density to the extraneous force arising from the exciting coil. But to regard μ as a physical property, the *permeability* of some particular substance and belonging to that substance in the same way that conductivity belongs to an electric conductor, is to remain blind to the discoveries of the last twenty years.

Turning to the suggestion put forward in Section (11) that pressure may be the controlling factor in the magnetic change, I fully share the difficulty Mr. Atkinson has expressed in forming any rational idea of the mode in which pressure might act on the orbits of the planetary electrons. We all believe pressure to be kinetic in origin, but it has to be remembered that the kinetic theory of pressure was formulated in days when atoms were assumed to be something like diminutive billiard balls. Possibly the classic theory of pressure will have to be recast when the structure of the electronic atom has been settled.

Mr. Watson gives us a happy simile for the state of things in hardened steel. But to complete his picture the crowd of human beings must be supposed to undergo some kind of transformation as fundamental as that of Beta iron into Alpha iron. We must imagine a crowd of Frenchmen changing into Englishmen as the result of a change in the climate. In all essentials Mr. Watson's view is that of the paper, but whether the whole of the energy of solution is released before the solute molecules have moved away from their solution positions is rather a moot point. Mr. Watson's experiment of heating a piece of hardened steel and looking for a possible release of energy, is one of great interest. I can readily understand how difficult it would be to secure the necessary precision (there is always a doubt clinging to a negative result), but the experiment certainly deserves to be repeated under stringent conditions.

Another matter referred to in the course of the discussion was the solubility of carbon in Alpha iron. This must not pass unnoticed, although it does not affect the general argument of the paper. I have made no experiments on solubility, and for facts outside my own observation I have relied on what I could glean from metallurgical textbooks. But on this question of the solubility of carbon in iron I could not find anything definite to go upon. To repeat what is said on pages 739 and 740, information as to solubility is scanty and vague. References are frequent to some unspecified degree of solubility in Alpha iron, but the solubility is implied rather than stated as a matter of observation or measurement. To co-ordinate this vague information with the known coercive force of softened steel, I made the simplest possible assumption; namely, that the solution of the carbide was the only source of potency that need be taken into account. In other words, I assumed that in softened steel any potency arising from carbide in the crystalline state would be very small and might safely be neglected. On this basis it appeared that about 0·26 per cent of carbon would be retained in solution in Alpha iron, a quantity in good agreement with the statements made by more than one metallurgical writer of eminence, as to the carbon content of steels that "could not be hardened."

But Mr. Kayser points out that it is possible to *see* the carbide in the crystalline state when the carbon content of the steel is so small as 0·1 per cent. The same criticism, and on the same ground, has reached me from another metallurgical quarter, and I suppose that what is seen in softened steel of very low carbon content is the crystalline structure known to the metallurgist as pearlite—a visible structure which is formed when the carbide Fe_3C and the Alpha iron undergo crystallization simultaneously. Then again, since the reading of the paper a brief note has appeared in *Nature* from which I gather that Prof. Honda has quite recently determined the quantity of carbon soluble in iron (presumably Alpha iron is meant) and finds it to be 0·035 per cent *). Clearly the metallurgical evidence is against me, and if our mental picture of the state of things in softened steel is to accord with the facts, the potency arising from the crystallized carbide must not be left out of account. That is to say, the coercive force of a piece of *softened* steel must not be attributed solely or even mainly to the pattern of solution, as it is in the paper. It must be thought of as arising from a more complicated pattern constituted partly by crystalline carbide, partly by solution. With this correction, the phrase surplus carbide, when it is used in the paper in connection with magnet steel containing about 0·7 per cent of carbon, must be interpreted as meaning more than nine-tenths of the whole amount of carbon in the steel, whereas throughout the paper the surplus is assumed to be about two-thirds of the carbon content.

* *Nature*, 1925, vol. 115, p. 656. The reference is to the Science Reports of the Tohoku University, vol. 13, No. 2. How the determination was made I do not know. I am writing this reply several hundred miles from the nearest metallurgical library and cannot refer to the original Report.

Another point of theoretical interest may be noticed. By means of a novel method of observation (the experiment is recorded in Fig. 12) I have shown that in a piece of tungsten steel containing 0·65 per cent of carbon, the time occupied by the surplus carbon in passing out of solution as the temperature fell from 708° to 650° C. was 2 minutes, as nearly as the time can be determined. Looking at Fig. 12, it is clear that the passage from solution to crystal must have begun at or a little before the point corresponding with 29 minutes on the time scale, where the energy curve begins to turn upwards. The process cannot have come to an end before the completion of the magnetic change at minute 31, a point which marks the end of the transformation from Beta iron to Alpha iron. Hence the time occupied by the passage from solution to crystal was certainly not less than 2 minutes. I see no escape from this conclusion and cannot accept Mr. Kayser's statement that the transfer process is an all but instantaneous affair. I do not know on what experimental results he founds his belief. I have, at various times, integrated numerous inverse-rate cooling curves, including those of Osmond, of Carpenter and Keeling and others, and in every case the duration of the transfer has proved to be considerably more than 2 minutes, often being as much as 5 minutes or even more. The experiment recorded in Fig. 7 is a case in point, the duration of the passage from solution to crystal being at least 6·5 minutes in this experiment.

Mr. Brookes dismisses the carbon-coercive-force curve for tungsten steel (Fig. 9) as untrustworthy, mainly on the ground that it is not in agreement with a number of coercive-force tests which he has collected from various sources. Mr. Woods is also reluctant to accept the double curve. I have already referred on page 742 to the extraordinary discrepancies in the figures when coercive-force values obtained by different observers are brought together, and it was the difficulty of making any sense of them that led me to investigate. The outcome was as contrary to my *a priori* notions as it is to the opinions of Mr. Brookes and Mr. Woods, but when my critics have had a little more time to study Section (10) and to note the precautions taken to ensure accuracy, I am confident that they will find themselves compelled, as I was, to accept the double curve, given in Fig. 9, as a fact.

Mr. Edwards has fallen into an error in supposing that the figures, given on page 766, for the present rates of decay in tungsten steel and cobalt steel include the decay which occurred during the first year after hardening. My figures for the annual change, namely 0·8 units and 2·0 units respectively, are based on the experimental data from which Fig. 21 and Fig. 22 were prepared, and represent the rates of decay (slope of the decay curves) at the end of the third year, as nearly as they can be determined. As I have pointed out in the paper, the intervention of the seasonal change makes a precise statement impossible for the first two or three years, and it would certainly be rash to base any estimate on a decay curve like that shown in Fig. 24. Several more years must elapse before we can obtain entirely trustworthy figures for the relative rates of decay in the two kinds of steel. In the meantime, I naturally prefer my figures to those of Mr. Edwards, and I believe they are not so very far from the truth. I agree that decay in time and decay by heat must be on all fours as regards the effect on the molecular pattern. In my opinion, decay in time is in fact decay by heat and, if that is so, nothing short of reducing the temperature of the hardened steel to absolute zero would put a stop to decay.

Replying to Mr. Woods, I hope before long to deal with magnetic measurement, especially as applied to magnet steel, and a description of my magnetometer must be deferred until then. I may, however, mention one feature which I believe to be unique:—the instrument contains no magnetic material of any kind whatever, other than the specimen of steel under test. For all work requiring accuracy test-pieces of ellipsoidal form are used, and the applied magnetic field being uniform throughout the length of the test-piece, coercive force is measured with great precision. In practice a number of readings are taken for each determination, and the probable error of the mean value is certainly nearer one part in a thousand than one in a hundred. In short, the error in the coercive-force values given in the paper is much smaller than the error involved in the determination of the carbon content of a small specimen of steel by the combustion process.

The effect of stroking a permanent magnet with a piece of iron has been referred to by Mr. Edwards and also by Mr. Kayser. What the stroking does is to break down the orientation of a superficial layer of the steel. How deep the effect goes I do not know, but there is probably a fairly well-defined limit to the mischief that can be done to a magnet in this way. As to the explanation, we may suppose the piece of iron to act as a magnetic shunt to the portion of magnetized steel which it covers. A local flux path is thereby created in which the iron, becoming magnetized, assists in generating the magnetic flux. Where the flux passes from the magnet to the iron and from the iron to the magnet, at the ends of the piece of iron, it is at right angles to the direction in which the steel is oriented. It would therefore exert a force tending very effectively to break up the orientation of the molecules of iron in the magnet, close to the surface of the steel. By moving the piece of iron to and fro along the magnet every part of the surface of the steel is subjected in turn to this local demagnetizing action, and in the absence of a coil field the superficial layer of steel remains wholly or partially demagnetized. By means of a coat of paint Mr. Kayser has shown that the stroking effect is greatly diminished by a small gap between the iron and the magnet. This is just what the Ampère-Weber-Ewing theory would lead us to expect.

The stroking of a permanent magnet with a bit of iron seems at first sight to be a trivial experiment, but a very little reflection shows how closely it approaches the fundamentals of permanent magnetism. In the course of a long acquaintance with permanent magnets, I have met with quite a number of odd phenomena of the kind, easily overlooked and appar-

rently of little importance. Perhaps their chief significance lies in the fact that they so readily fit into their right places when they are interpreted in the light of the theory just now referred to. I wonder whether it will be possible to explain them when the present-day physicist has succeeded in destroying all the well-tried classical theories, without providing anything to take their place.

I come now to the important question raised in the discussion with regard to the economic status of magnet steels in which chromium is used to impart potency, chromium carbide having a far greater power in that respect than the other potency-giving carbides known to us. Mr. Watson and Mr. Kayser take exception to the comparative figures given in Table 9, on the ground that I have underrrated cobalt magnet steel both by placing too little energy to its credit and by taking an excessive price. Mr. Watson founds his objection to my figures on the magnetic energy guaranteed by the steelmaker and on a hypothetical calculation of the price of cobalt steel as the buyer would like it to be. But I can only speak of cobalt steel as I find it, and the energy value given for it in Table 9 is the highest figure I have so far obtained. It is true that much higher energy values are constantly claimed for cobalt steel, but I have yet to see these claims substantiated by properly authenticated demagnetization curves. Ever since the announcement of Prof. Honda's discovery of cobalt magnet steel, a sporadic shower of samples of this steel has descended on Acton Lane Works, and it has been a matter of keen interest to Mr. Finnis and myself to obtain the best possible result from each sample. When the steelmaker supplying the sample has furnished instructions as regards heat treatment and hardening these have been strictly followed, but up to the present time not a single specimen of cobalt magnet steel received by my firm has fulfilled the claims made for it, both the coercive force and the available energy falling a long way short of the values put forward by the various steelmakers who supplied the samples. For example, one of the best of the samples, when tested 18 hours after the hardening, gave the demagnetization curve reproduced in Fig. 23. In this curve the maximum product of co-ordinates is about 690 000, corresponding with $e = 27\,500$ ergs, a figure lamentably short of what is claimed for good cobalt magnet steel.

It is not for me to explain the great disparity between what is claimed for cobalt magnet steel and its actual performance. It is the business of the seller to substantiate his claims. But I may point out that cobalt steel appears to be peculiarly liable to spoiling in manufacture. Moreover, it would seem that some special heat treatment is needed to effect a complete magnetic cure of the ultraheated condition. But if this is so, the buyer has been left to find out these things for himself, no steelmaker having ever said a word to suggest that he was supplying magnet steel in a spoiled condition, nor given a hint about the magnetic effect of what I have called the ultraheated state. I do not for a moment believe that the steelmaker—honest man—was aware of the mischief he was doing. If he had been, he would surely have set about finding a remedy. He could not be expected to say anything helpful about spoiling and ultraheating so long as he knew nothing about them. But now, in view of the facts disclosed in the paper, he cannot help knowing.

Some of my critics seem doubtful about the composition of the sample of cobalt steel included in Table 9. Analyses were duly made of each of the three samples in the table and, to set any doubt at rest, I give them here in Table 9A. The analysis of

TABLE 9A.

Analyses of the Magnet Steels included in Table 9 (page 771.)

Element	Carbon steel	Tungsten steel	Cobalt steel

Cobalt ..	Nil	Nil	31·615
Carbon ..	0·687	0·725	0·728
Tungsten ..	Nil	6·130	6·435
Chromium ..	Nil	0·094	2·870
Aliens ..	0·399	0·643	0·537
Total ..	100·000	100·000	100·000

the cobalt steel discloses an excess of tungsten, but otherwise there is little to take exception to. Assuming the iron-cobalt alloy to be represented by Fe_2Co, we must multiply the percentage of iron by $58\cdot97/(55\cdot85 \times 2)$, in order to arrive at the correct percentage of cobalt. Doing the sum, it will be found that 57·8 per cent of iron requires 30·5 per cent of cobalt. This compares with 31·6 per cent found by analysis, and disposes of the supposition that any deficiency in magnetic energy arose from a deficiency in the content of cobalt. As stated on page 771, this sample of cobalt steel, when tested in the condition in which it was received from the steelmaker, only gave $e = 23\,800$. There was therefore good reason to suspect that the steel had been badly spoiled in course of manufacture, and in order to obtain a better figure a piece of the rolled bar was "restored" by Mr. Finnis. From magnetometer test-pieces, machined from the central core of the rolled bar after its restoration, we obtained the value $e = 30\,300$ ergs per cubic centimetre. This being the highest value I have observed in cobalt steel it was included in Table 9 as making a strictly fair comparison with the tungsten steel specimen, the latter also giving the best energy value I have so far obtained from tungsten steel. The prices given in the table are not hypothetical figures. They are the actual prices charged by the steelmakers for the particular steels, for quantities of a ton or more. Mr. Kayser and Mr. Watson regard these prices as excessive and I am sure that any buyer would be of their opinion. To-day, as Mr. Kayser points

out, cobalt magnet steel is somewhat less expensive. But so is tungsten steel and, roughly speaking, the relative prices are much about the same. In short, energy for energy, tungsten steel is still a very long way ahead of cobalt steel on the score of cost. Of course, there are various technical advantages to be gained by the use of cobalt steel. These are set forth in the paper on pages 771 and 772, and the figures given in Table 9 show very clearly that we cannot have those advantages without paying for them in a largely increased cost for steel. That the information conveyed by the table is unpalatable I can well believe. But facts are stubborn things, and when they are contrary to our hopes they are peculiarly disagreeable.

The question remains whether the best possible magnetic result has yet been obtained, either from cobalt steel or from chromium steel. In the light of knowledge gained in recent years, I cannot help thinking that very considerable improvement is possible. Hitherto, as I have said, steelmakers do not appear to have been aware of the mischief they were doing. At all events they have one and all been content to make magnet steel without paying any attention to spoiling. But now that spoiled tungsten magnet steel and its restoration have been investigated—incidentally at the sole cost of a firm entirely outside the steel-making industry—it may be hoped that the steel-makers will embark on similar investigations of the spoiling that occurs in cobalt steel and also, as I believe, in chromium steel. The other cause of magnetic deficiency, ultraheating, has yet to be mastered. So far as tungsten magnet steel is concerned I think the Appendix to the paper gives all the information which the magnet maker needs to effect the complete curing of the ultraheated state. But in any steel which, like cobalt magnet steel, contains chromium as a potency-giving agent, the ultraheated condition appears to be far more persistent. So much so, that repeated heatings to, and coolings from, the appropriate curing temperature fail to restore the steel completely to the normal magnetic state.* In short, the curing of ultraheated magnet steels which contain chromium calls for systematic investigation, and I suggest that it is now the turn of the steelmaker to undertake a troublesome task. In my belief, research along the lines followed in the Appendix would be amply rewarded. It would not be surprising if the result were to bring chromium magnet steel up to the economic level of tungsten steel, or even above it, and a corresponding improvement might well be effected in cobalt magnet steel. But it must be borne in mind that magnet steel is not a subject for rough-and-tumble experiments; scientific method and precision are essential, more particularly in the magnetic measurements.

The foregoing paragraph must stand for my answer to the references made in the discussion to steels which contain chromium, including chromium magnet steel. I am acquainted with the flywheel ignition magneto of the Ford car and was interested to learn from Mr. Watson that the many magnets it contains are made of chrome steel. But this piece of evidence does not remove my scepticism any more than Mr. Ford's "Peace Ship" removed the warlike atmosphere of Europe. Only a demagnetization curve will convince me, and magnetic evidence of that kind is wanting. The only magnetic data I have seen relating to chromium magnet steel showed it to be decidedly inferior to tungsten steel on the basis of energy and cost. But that was some years ago, and maybe the American steelmaker has improved chromium steel. If that is so, surely it would be a simple matter to produce a few trustworthy demagnetization curves? They would be more convincing than any number of words. I have not, myself, made any experimental examination of chromium magnet steel. It has been quite enough for one experimenter to make a thorough examination of tungsten magnet steel.

In conclusion, I am heartily in agreement with Mr. Brookes when he says that the question of spoiled steel is the most important problem before the magnet steel industry to-day, and that it will have to be dealt with. The fact that magnet steel is spoiled in the making has too long remained in the dark. The truth was bound to emerge sooner or later, and now the cat has been let out of the bag. A few years ago when I first discovered decomposed magnet steel I had to invent a phrase to describe it, *spoiled steel*. At that time makers of magnet steel—with one notable exception—professed to disbelieve in the existence of spoiled steel. To-day we find steelmakers all willing enough —to talk about it. It is an encouraging sign. The ferment is already at work, and when the buyer begins to reject spoiled magnet steel, the stick will begin to beat the dog and sooner or later the old woman will manage to get the pig over the stile. Let us hope that this event will take place in Sheffield, and without protracted delay. It would be only too easy to wait for unspoiled or restored magnet steel to be introduced into England as the latest improvement made by the foreign steelmaker.

* See, for example, an illuminating experiment by Dr. Edwards, in which a specimen of tungsten-chromium tool steel in the ultraheated state failed to return completely to the normal state (judged by the course of the inverse rate curve) after three heatings to 900° C. How many more heats would have been needed to effect a complete cure in the magnetic sense, it is not possible to say. C. A. EDWARDS: "The Physico-Chemical Properties of Steel," p. 187, Fig. 148.

THE ECONOMIC ASPECT OF THE UTILIZATION OF PERMANENT MAGNETS IN ELECTRICAL APPARATUS.

By E. A. Watson, O.B.E., Associate Member.

(*Paper first received* 10*th March, and in final form* 23*rd June*, 1924; *read before the* Scottish Centre 7*th April*, 1925.)

Summary.

The paper first describes the principal types of steels at present available for the production of permanent magnets, and gives magnetic data for typical examples. The cost of these steels is then considered, and figures are given for the actual cost of the material of the steels for which magnetic data have been furnished. Consideration is then given to the other costs involved in working and hardening the steel and housing the finished magnet, and a total figure is obtained which enables a comparison to be made of the various steels under different conditions. It is shown that under certain conditions the use of a cobalt steel will affect an economy over a tungsten or chrome steel, while under other conditions the reverse is the case.

Comparison is then made between the cost of providing a given flux by an electromagnet and also by a permanent magnet, allowance being made for the value of the power consumed in the former case. In order to obtain these data an investigation is made of the most economical winding depth of the electromagnet. The result obtained is applied to two typical cases, and it is shown that in small d.c. machinery considerable saving might be effected by the use of permanent fields, particularly where the cost of fuel is high or where the apparatus runs for long hours, and special applications to certain classes of service are suggested.

Finally, some typical examples are considered of the applications of permanent magnets and particularly of cobalt steel magnets, including magnetos, small d.c. generators, alternators, motor-generators, and certain special applications,

Table of Contents.

1. Introduction.

With the introduction during the last four years of the cobalt magnet steels the problem has arisen, first, as to under what conditions such steels can be economically substituted for the older tungsten and chrome steels, and, secondly, to what extent their use might be considered in electrical machinery in which electromagnets have previously been employed. The problem is in most cases purely one of economics, involving a consideration of the relative cost of obtaining a given magnetic flux with the different materials available; but although theoretically the problem is capable of simple solution the actual choice of material is not so easy, owing to the difficulty of accurately evaluating the incidental costs which are not a direct function of the amount of magnetic material employed. While, therefore, it is hoped in this paper to be able to indicate broadly the lines along which development may take place, it is not the author's intention to attempt to lay down any hard-and-fast lines of demarcation between the fields which are best served by any particular class of material.

2. Steels Available for Permanent Magnets.

At the present time (1924) the following materials are available as marketed products, and are regularly employed for permanent-magnet work :—

(*a*) *Chrome steel*, containing about 2 per cent chromium with 1 per cent of carbon. This steel is largely used in America and on the Continent. Its development received considerable attention during the war in countries where tungsten was not available. It is an oil-hardening steel, fairly simple in heat treatment.

(*b*) *Tungsten steel.*—This steel, which has largely been used in this country for magneto magnets, and also in the better class of magnets for instruments (meters, etc.), contains about $5\frac{1}{2}$ per cent tungsten,

from 0·55 to 0·8 per cent carbon, and occasionally about 1 per cent chromium. It can be made for either water- or oil-hardening. Its heat treatment requires some care owing to the risk of distorting and cracking, especially when high coercive forces are aimed at.

(*c*) *Low- and medium-cobalt steels.*—A large number of steels have been made at different times with cobalt percentages ranging from 6 per cent upwards, but the majority have had only a brief commercial existence, and at present this class is represented by a cobalt-chromium series of steels. These are air-hardening steels, containing about 9 per cent chromium, with 0·8 to 1 per cent carbon. A small amount of other alloys, such as tungsten or molybdenum, is added to help the air-hardening properties, and the cobalt content usually ranges from 9 per cent to 20 per cent.

The heat treatment of these steels is somewhat complicated, but on the other hand does not require such accurate temperature control as do the other steels. It usually consists in a preliminary heating to 1 150° C. in order to break up the complex carbides which are present in the annealed bar, and to ensure thorough solution of the carbides. This is generally followed by a quick annealing at about 750° C. to break up the austenite formed at the previous treatment, and this again is followed by heating to about 1 000° C. and cooling in air. Considerable latitude can be given on the temperatures of the first two treatments, and a tolerance of ± 20 deg. C. can usually be allowed on the latter, but careful control of the cooling rate is necessary. These steels are remarkably free from troubles due to cracking and distortion.

(*d*) *High-cobalt steels (Japanese steel).*—These steels usually contain about 35 per cent cobalt, the percentage corresponding to the alloy Fe_2Co, which gives maximum magnetic properties. A large number of these have been produced employing chromium, tungsten, molybdenum and manganese as alloying agents to enhance the effect of the cobalt, although a plain cobalt-carbon steel with this percentage gives fairly good results. A very common composition contains from 3 to 4 per cent tungsten, 1 to 2 per cent chromium and 0·8 per cent carbon, with small quantities of manganese and 35 per cent to 36 per cent cobalt.

These steels are all oil-hardening with a single treatment only. They give little trouble with distortion or cracking, but accurate temperature control is essential, as a slight elevation of temperature above the absorption point promotes the retention of austenite with a low remanence. The cooling rate is also of importance, and it is hence important to use an oil of the correct viscosity and to control its temperature.

Magnetic properties.—It will be readily realized that it is a somewhat difficult matter to lay down the magnetic values of the various steels. Any given steel will, in general, even with the most careful heat treatment, give results which, taken over a batch of magnets, may vary as much as 10 to 15 per cent above and below the average figure for the batch. The maker of the steel, naturally wishing to take the most sanguine view, will frequently quote a figure nearer to the maximum than to the average, while on the other hand if a guaranteed minimum is required, the figure will, of course, be below the average value.

Representative curves for the different steels are given in Fig. 1, while the figures given in Table 1 are taken as representing the average values of $(BH)_{max.}$, which, after all, is the true criterion of any magnet.

TABLE 1.

Material	$(BH)_{max.}$	Stored energy per cm³ of magnet
		ergs
Chrome-carbon steel	230 000	9 200
Tungsten steel..	260 000	10 400
Cobalt-chrome, 9 per cent Co	500 000	19 900
Cobalt-chrome, 12 per cent Co	580 000	23 000
Cobalt-chrome, 15 per cent Co	650 000	25 900
Cobalt steels, 35 per cent Co	800 000	31 800

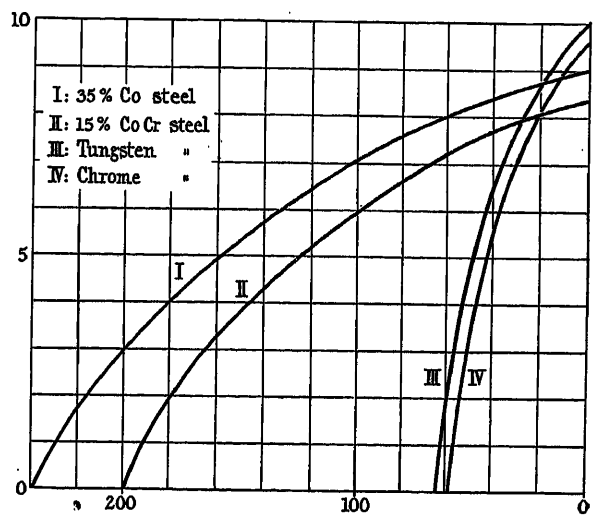

FIG. 1.—Magnetic data for commercial magnet steels.

With the exception of the chrome steels the figures given in Table 1 represent the average values of over 400 000 magnets of which records have been kept during the past few years. They probably represent fairly present-day practice with these steels, but it is, of course, possible that improved results may be obtainable with slight modifications in composition or heat treatment.

Relative costs.—The statement of the cost of a magnet steel is a more difficult problem than the equivalent statement of its magnetic properties, for while the latter is a definite function of its composition and heat treatment, the former depends on many other factors than the composition alone. Even assuming a definite basic price of raw materials, iron alloy, etc., the price of the magnet steel must depend upon other factors, such as the relative difficulty of melting, forging, cogging and finishing, and also upon the amount of scrap produced. Some steels are comparatively easy to work and give sound ingots requiring but little

grinding, and little scrap. Here, again, one must not lose sight of the fact that the ordinary chrome and tungsten steels have been produced in large quantities for many years, and the technique of their manufacture is well understood. Further, competition between steel firms has ensured that their production has been brought down to an economic basis, and that this production is attended with the minimum amount of scrap.

The cobalt steels are at present produced by but few firms. Their production has involved a large amount of experimental work, the costs of which have to be covered, and there is not the same certainty as regards the requisite allowances for waste and scrap. In addition, the price of metallic cobalt is at present a somewhat uncertain factor, as the available sources of supply are few in number and the possible extent of the world's resources is not known with great certainty. Moreover, the refining and distribution of the metal are in the hands of a small number of individuals. During the past three years cobalt has been offered at prices ranging from 10s. to 30s. per lb. Instead, therefore, of actually giving the present quoted prices of cobalt magnet steels, which the author feels can only be regarded as transient, it is proposed to take a basis price equivalent to a tungsten steel, and to add to this the value of the cobalt content estimated at the price of 12s. 6d. per lb. This, it is felt, may be taken as corresponding to a price for the metal of 10s. per lb. plus 25 per cent allowance for scrap, waste and handling charges.

On this basis the prices of the various steels in annealed bar are taken as follows :—

	Pence per lb.
Chrome-carbon steel	6
Tungsten steel	12
9 per cent cobalt steel	25·2
12 per cent cobalt steel	30
15 per cent cobalt steel	34·5
35 per cent cobalt steel	65

3 (*a*). Comparison of Relative Costs of Various Permanent Magnet Steels.

The cost of producing a given flux by means of a permanent magnet is in reality the sum of two quantities, viz. :—

(1) The cost of the magnet itself; and
(2) The cost of housing the magnet.

The former quantity can generally be estimated fairly closely for any given magnet steel, but the latter is a far more difficult problem. It must in any case depend upon the class of apparatus in which the magnet is employed. In certain cases the dimensions of the apparatus as a whole will be determined by the dimensions of the magnet, so that a reduction in magnet dimensions may effect a large saving. In other cases a reduction in magnet dimensions will enable little or no consequential saving to be obtained. For example, in a moving-coil instrument the dimensions of the case are generally determined by the necessity of providing a given size of scale, so that no reduction in overall dimensions could be effected by using a smaller magnet of better material. On the other hand, in an ignition magneto for automobile work, it is the usual practice to make the framework of the machine and cast end-plates conform to the shape of the magnets, so that any reduction in magnet dimensions will bring about a reduction in the amount of gunmetal or aluminium employed, and, by rendering simpler construction possible, may reduce labour costs and charges.

Certain applications arise, of which examples will be given later, where the saving possible by adopting a high-grade steel is out of all proportion to the cost of the steel itself, and in what may be termed the limiting case we have examples where results obtained by such a steel could not under any conditions be obtained in any other way. It is obvious, therefore, that no general expression can be found to take into effect the cost of housing the magnet itself, and the allowance for this must be left in every instance to be determined from an examination of the conditions prevailing in the case in question.

The cost of the magnet may be divided roughly into the following :—

(i) The cost of the steel;
(ii) The labour and charges involved in the necessary work required to bring the magnet to the finished shape and dimensions; and
(iii) The labour and charges involved in hardening the magnet.

(i) *The cost of the steel* has already been dealt with, but it remains to express the material cost given under this heading in terms of the cost per magnetic unit, or per erg of energy stored. In order to save working in very small fractions of a penny, it is proposed to take, as a convenient unit, the quantity 39 800 ergs, corresponding to a value of (flux × M.M.F.) equal to 1 000 000. This would therefore be equivalent to providing a flux of 1 kiloline against an M.M.F. of 1 000, 10 kilolines against an M.M.F. of 100, and so on. Taking this as a basis we obtain Table 2.

Table 2.

Relative Material Cost for Providing 1 *Kiloline of Flux against an M.M.F. of* 1 000.

Material	Volume required	Cost per cm^3	Total cost
	cm^3	d.	d.
Chrome-carbon	4·34	0·105	0·457
Tungsten	3·88	0·211	0·820
Cobalt-chrome (9 per cent)	2·00	0·442	0·884
Cobalt-chrome (12 per cent)	1·73	0·529	0·910
Cobalt-chrome (15 per cent)	1·55	0·608	0·940
Cobalt (35 per cent) ..	1·25	1·14	1·420

From the table it will be seen at once that, given equal conditions in other respects, we cannot expect to obtain

any saving in material costs by employing a better grade of steel.

(ii) *Labour and charges involved in shaping the magnet.*—As in the case of the cost of housing the magnet, it is not possible to obtain any general expression for the cost of bringing the magnet to the desired shape. It is clear, however, that in the majority of cases this will not be the same for a low-grade magnet as for a high-grade one performing the same duty. In most applications it will be found that the low-grade steel has to be bent to a horseshoe or similar shape in order to accommodate the necessary magnetic length, while the high-grade steel can frequently take the form of straight bars, which are merely cut off and hardened. Consequently, much more labour and plant are necessary to deal with the low-grade magnet than with the high-grade one. Further, any bending operation must be done while hot and the bending has frequently to be followed by annealing, introducing fresh charges for fuel, plant upkeep, and depreciation and labour. Even assuming that the high-grade steel undergoes the same operations, the mass of steel to be handled is greater, so that more heat units are involved in its treatment and greater furnace capacity is necessary, while incidental charges, such as transport, are higher for the low-grade steel. Further, if grinding operations are necessary upon the magnet, the area to be ground and the amount of metal which has to be removed are almost certain to be considerably greater in the case of the low-grade material.

All things considered, we shall probably not go far wrong in making the assumption that the labour costs involved are directly proportional to the weight of the magnet. In the case where a bent low-grade magnet compares with a straight high-grade one this assumption will probably favour the former. In the case where both magnets are of the same general shape the high-grade one will be favoured, so that here again our conclusions must be modified in the light of any particular case which is under consideration. In order to embrace different classes of magnets of varying degrees of complication, three different series of labour costs have been chosen, viz. 3d., 6d., and 1s. per lb. of magnet, corresponding to 0·053, 0·106, and 0·212d. per cm^3 of magnetic volume. This, combined with the figures given in Table 2 for the cost of material only gives us Table 3.

It will be noticed from Table 3 that while for magnets of simple shape the low-grade chrome steel still shows to advantage compared with all the others, for more complicated shapes the cobalt-chromium steels show a decided advantage, while under practically all conditions the tungsten steels show up badly as compared with both their lower- and higher-grade rivals. The high-cobalt steel is, however, at a disadvantage under all conditions.

(iii) *Cost of hardening.*—Although the cost of this item lends itself to more exact computation than the foregoing, this also is a quantity which may vary between wide limits. Not only will it depend upon the cost of fuel, whether coke, town gas, producer gas or electricity, but it will also depend—as far as the labour in hardening is concerned—upon the relative intricacy of the magnet. For example, a long, bent magnet of complicated shape will require quenching in special clamps. This operation must be done carefully, one magnet at a time, by a relatively skilled operator. On the other hand, straight magnets of an air-hardening cobalt-chrome steel may be handled by comparatively unskilled labour without the use of any cooling jigs or clamps, and can be withdrawn from the furnace just as quickly as it is possible to pick them up with the tongs. There is no doubt, in fact, that for really large production of magnets of this class a travelling conveyer could be employed, and the human element almost entirely dispensed with. On the other hand the cobalt-chrome steels, as at present employed, require in general a triple heat treatment, so that both the costs of heating and of labour are greater than for steel with a single treatment only.

The author's experience is that the furnace capacity and labour required for treating a steel of this class is approximately double that necessary for the same weight of a single-treatment direct-hardening steel. It is believed that, taking the one extreme with labour, fuel, and overhead charges cut down to their minimum, and with a well-designed plant working at its maximum efficiency, the heat treatment might be carried out at an inclusive figure (labour, fuel and charges) of 2d. per lb. for single-treatment steels and 4d. per lb. for triple-treatment steels. The same figure has been

TABLE 3.

Relative Costs of Material plus Labour and Charges up to Point of Hardening.

Material	Volume	Material cost	Labour + charges at, per lb.			Total at, per lb.		
			3d.	6d.	1s.	3d.	6d.	1s.
	cm^3	d.	d.	d.	d.	d.	d.	d.
Chrome	4·34	0·457	0·231	0·462	0·924	0·688	0·919	1·381
Tungsten	3·88	0·820	0·205	0·410	0·820	1·025	1·230	1·640
Cobalt-chrome (9 per cent)	2·00	0·884	0·106	0·212	0·424	0·990	1·096	1·308
Cobalt-chrome (12 per cent)	1·73	0·910	0·092	0·184	0·368	1·002	1·094	1·278
Cobalt-chrome (15 per cent)	1·55	0·940	0·082	0·164	0·327	1·022	1·104	1·268
Cobalt (35 per cent)	1·25	1·420	0·066	0·132	0·264	1·486	1·552	1·684

assumed for single-treatment chrome and tungsten steels as for high-cobalt steels, it being assumed that the extra labour involved in quenching the chrome or tungsten steel magnet of horseshoe or other complicated shape is balanced by the fact that the cobalt steel must be heated to a higher temperature, viz. 950° C. as against 850° C., and that its heat absorption is greater, necessitating the supply of more heat units to complete the solution of the carbides. With small outputs, less efficient plant and expensive fuel, there is no doubt that the figures given of 2d. and 4d. per lb. might be exceeded and the hardening costs easily run up as high as 6d. and 1s. respectively.

Taking these values and adding them to those of Table 3 we obtain the figures given in Table 4.

Conclusions to be drawn from a study of Table 4.—(1) In no case does the tungsten steel magnet show up to advantage, either as compared with the chrome steel on the one hand, or the cobalt-chrome series on the other, although it does in certain cases compare favourably with the high-cobalt steel.

(2) The chrome steel magnet is the cheapest when the shapes are simple, and the labour and hardening costs are low, but is more expensive than the cobalt-chrome series when the magnets are at all intricate in shape, or when hardening costs are high.

(3) In no case does the 35 per cent cobalt steel show any advantage over the cobalt-chrome series. Except for very special work, where maximum results must be obtained irrespective of cost, the use of this steel does not appear to be economically justifiable.

(4) There is little difference between the various grades of the cobalt-chrome series, except where the hardening and labour costs are excessively heavy. In this case the steel with the highest percentage of cobalt shows a saving in cost.

Effect of cost of housing magnet.—As we have already indicated, it is not possible to obtain a formula which will make allowance for the cost of housing the magnet, and any given case must be worked out on its merits. It is, however, possible to see in a general sort of way to what extent the costs obtained for the magnet itself will require modification, so as to take the cost of housing into account. In meters and measuring instruments we have already seen that it is very problematical whether any reduction in the cost of housing can be obtained, while in magnetos and small generators, in which the magnets are closely embraced by a non-magnetic structure of brass or aluminium, some saving may be looked for.

Leaving on one side any question of saving due to simplification in design, there are probably but few cases in which the saving in structural material, consequent upon a change from chrome steel to cobalt steel (to take an extreme case) would exceed 30 per cent of the weight of the magnet itself estimated as brass, or 20 per cent when estimated as aluminium. This at the usual market prices at present ruling would correspond to an addition of some 4d. to 5d. per lb. to the net material cost of the chrome steel magnet, and would raise all the figures in the top line of Table 4 by approximately 0·3d., while those for the tungsten steel magnet would be raised by a slightly smaller amount. If this allowance be made for the saving in cost of housing, it will be seen that under practically all conditions the cobalt-chrome series compares favourably with the chrome steel and is distinctly economical as compared with tungsten steel, and it would seem that there should be a strong inducement to make use of steels of this series in many of the present applications of permanent magnets, and particularly so in the case of magnetos for internal-combustion engines where a saving in weight or dimensions is always looked on with favour by the user.

On the other hand it must be pointed out that the prices we have assumed for the cobalt steels are lower than those at which these can be obtained at the present time. This discrepancy in price is probably due to the following factors, among others:—

(1) Increased difficulty in working of the high-chromium alloys, which retain their rigidity up to high temperatures and are consequently difficult to forge.

TABLE 4.

Total Works Cost of producing Magnets to give a Value of Flux × M.M.F. = 1 000 000.

Material	Good hardening: Hardening cost	Good hardening: Total cost A	Good hardening: Total cost B	Good hardening: Total cost C	Bad hardening: Hardening cost	Bad hardening: Total cost A	Bad hardening: Total cost B	Bad hardening: Total cost C
	d.	d.	d.	d.	d.	d.	d.	d.
Chrome	0·153	0·841	1·072	1·434	0·459	1·147	1·378	1·840
Tungsten	0·136	1·161	1·366	1·776	0·408	1·433	1·638	2·048

Cobalt (35 per cent)	0·044	1·530	1·596	1·728	0·132	1·618	1·684	1·816

NOTE.—The headings A, B, C to the columns indicate values of "labour + charges" as given in Table 3 of 3d., 6d., and 1s. per lb. respectively.

(2) Greater loss in metal in grinding and trimming operations.
(3) The natural desire of suppliers to recoup the cost of their original development work within the shortest possible time.
(4) Lack of complete data as to causes of scrap and possible scrap percentage which may occur.
(5) The comparatively small quantities in which the alloys are made at the present time, with the high attendant costs for fuel, labour and overhead charges.
(6) Uncertainty as to stability of prices of metallic cobalt.

As regards items (1) and (2), it is to be hoped that extended experience in manufacture will lead to the discovery of means of overcoming the high attendant costs under these headings, or possibly that research may lead to the discovery of an alloy with easier working properties and yet giving the same magnetic results. Item (3) is merely a temporary factor which will gradually decrease with extended use of the material and increased competition, while item (4) also will doubtless decrease as extended experience in the technique of manufacture becomes available. Item (5) is, of course, dependent upon the other factors and cannot be attacked directly, but reductions under this heading may undoubtedly be looked for, in so far as the use of the steel becomes more extensive. Item (6) is probably one of the most important factors operating, and is the one to which particular attention should be paid. The production of cobalt has in the past been secondary to that of silver, cobalt being a by-product from the silver ores of certain districts of Ontario. Latterly, however, cobalt deposits have been discovered in other parts of the world, notably in Australia, and it would appear that, given the certainty of an extended application of the metal, its development might be increased to a very considerable extent. It is not intended to deal in this paper with the production of the metal nor with the extent of supplies available, as it is felt that the best means of drawing attention to the possibility of the commercial exploitation of these is to define the conditions under which an extended use of the metal would be economically justifiable.

In particular it is desired to point out the disastrous results which would follow an artificial inflation in price such as occurred in 1920–21 when the price of the metal was forced up to 30s. per lb. Such a step would render absolutely hopeless any attempt to use it on a commercial scale as a constituent of magnet steel.

3 (*b*). Comparison with Electromagnet.

The simplest consideration of any ordinary application of an electromagnet will show at once that the M.M.F. per cm length of the wound portion of the magnetic circuit is so much higher than is possible with tungsten or chrome steel that the substitution of such a magnet for the electromagnet could only be made possible by a pronounced alteration in general design. In the case of cobalt steels, however, which can be worked normally at values of H ranging from 120 to 160 or higher, the length of cobalt steel required to replace a wound core is generally of the same order of magnitude, and the substitution can often be made without such drastic structural alterations as would otherwise be necessary. The problem then becomes one which is capable of mathematical treatment, although it is not, of course, possible to obtain any general formula, applicable to any case of an electromagnetic system, which will tell us immediately whether or not a saving can be attained by the substitution of permanent magnets. Every system must, for really accurate results, be examined on its own merits. It is possible, however, from a general consideration to arrive at conclusions which may give some idea as to whether a given problem is worth more detailed investigation or whether the suggested alteration can be immediately dismissed as unlikely to be of economic value.

In comparing the permanent magnet with the electromagnet, we have on the one hand to consider the cost of the steel and of its working and hardening, on the basis already outlined under the first section of this paper. On the other hand we have to take into account the following factors :—

(1) Cost of iron core.
(2) Cost of insulation.
(3) Cost of winding.
(4) The necessary labour and overhead charges on the foregoing three items.
(5) The capitalized value of the energy wasted in the magnetizing coil.
(6) Any accessory apparatus which can be dispensed with when a permanent magnet is employed.

This latter item is not amenable to general calculation, as it depends entirely upon the specific purpose to which the magnet is to be applied. In some special cases this factor may be the predominating one, e.g. in a small alternator the use of a permanent field may save the expense of a separate exciter, while in a dynamo it might enable a field regulator and a certain amount of wiring to be dispensed with. Again, in the case of a motor the direction of rotation of which had to be reversible from a distance, the use of the permanent field would effect a considerable saving of copper in cables, etc.

Let us, however, leave out item (6) as applying to special cases only, and consider only the economic aspect of direct substitution of a piece of permanently magnetized cobalt steel for one of soft iron surrounded by its necessary winding.

Imagine a circular magnet of length 1 cm to supply flux to an external circuit of constant magnetic reluctance. Let a be the radius of the magnet, and b that of the outside of the magnetizing winding, and neglect for the moment the insulation round the core, so that a is also the internal radius of the magnetizing winding. Consider the winding as consisting of one turn per cm only, and let ρ denote the specific resistance after making due allowance for the space factor of the copper and insulation.

Then, considering a section of the magnet 1 cm long, we have :—

Area of cross-section of winding $= b - a$
Mean length of turn $= \pi(b + a)$

$$\text{Resistance} = \pi\rho\frac{b + a}{b - a}$$

If I be the current flowing, watts $= I^2R$

$$= \pi I^2\rho\frac{b + a}{b - a}$$

$$\text{and M.M.F. per cm length of magnet} = \frac{4\pi}{10}I.$$

If the latter quantity be fixed, I also becomes fixed, and we have :—

$$\text{Watts lost per cm} = \text{Constant} \times \frac{b + a}{b - a}$$

This quantity, infinite when $b = a$, tends to a lower limit as b is increased indefinitely, but it never vanishes. Hence, no matter how much winding may be put on, a certain waste of energy is inevitable. The lower limit when b is large is :—

$$\text{Watts per cm length} = \pi I^2\rho.$$

This quantity does not contain the dimensions of the magnet involved, hence in the case of an electromagnet it requires no more energy in the limiting case to provide the magnetizing force in a large magnet than in a small one. So that, as far as energy consumption is considered, the magnetic system is clearly more likely to offer possibilities for the use of cobalt steel when the system is of small dimensions.

The value of $4\pi I/10$ for the electromagnet depends only upon I, the current passing, and is limited in general by conditions of heating, apart from economical considerations.

Determination of value of I necessary to make electromagnets equivalent to permanent magnets.—For the two magnets to be equivalent the values of M.M.F. available outside the magnet must be equal. In the case of a properly designed permanent magnet this is equal to the value of H at the point of $(BH)_{max.}$ multiplied by the length of the magnet. As a basis of comparison let us take the 15 per cent cobalt-chrome steel, the properties of which are given in Table 1. This steel has a $(BH)_{max.}$ of 650 000, occurring approximately at $H = -130$, the corresponding value of B being 5 000. Since a value of H of 130 corresponds to $I = 130/1{\cdot}257 = 104$, we obtain for the minimum value of watts per cm length

$$\pi \times 104^2 \times \rho = 3{\cdot}4\rho \times 10^4$$

The value of ρ will vary from $1{\cdot}67 \times 10^{-6}$ for cold copper, with unity space factor, up to as much as 10^{-5} for fine windings. We may take the usual range as being from $4{\cdot}5 \times 10^{-6}$ for heavy windings to 9×10^{-6} for ordinary d.c.c. wire in fairly small gauges. The watts per cm length then range between 0·15 and 0·30.

This comparison, it should be noted, is favourable to the electromagnet, as it presupposes the whole of the M.M.F. to be available externally. Actually this is not so, as a certain proportion will be necessary to overcome the reluctance of the iron itself. If the flux density is fairly low, say B not greater than 10 000, the error will only be of the order of 10 per cent, increasing the value of the loss by this amount in the case of the electromagnet.

The minimum loss figure is not, however, the value which can be usually taken, as it holds only for a winding of infinite depth. If we take a value of $b = 2a$, which represents the maximum winding depth usually employed, the loss figure will be increased in the ratio of 3 to 1.

The most economical winding depth is a matter which requires considering in the light of the cost of the material and of the power wasted. The volume of copper per cm length is

$$\pi(b + a)(b - a) = \pi(b^2 - a^2)$$

and its value is

$$p_c\pi(b^2 - a^2)$$

where p_c, the cost per cm³ of copper + insulation + labour cost and charges, varies from about 0·125d. for heavy wires to 1·5d. for fine wires of the order of 40 S.W.G.

The energy loss is, as we have seen,

$$\pi I^2\rho\frac{b + a}{b - a}$$

The capitalized value of the energy loss will be

$$\frac{100}{p}nk\pi I^2\rho\frac{b + a}{b - a}$$

where p is the rate of interest allowed on capital cost, $n =$ (number of hours worked per annum $\div$ 1 000) and $k =$ cost of power per kWh.

The total capitalized cost is given by the expression

$$\pi p_c(b^2 - a^2) + \frac{100nk}{p}\pi I^2\rho\frac{b + a}{b - a}$$

We may write this as

$$\text{Capital cost} = \alpha\left[(b^2 - a^2) + \beta\frac{b + a}{b - a}\right]$$

where

$$\alpha = \pi p_c \quad \text{and} \quad \beta = \frac{100nk}{p}\cdot\frac{\pi I^2\rho}{\alpha} = \frac{100nkI^2\rho}{pp_c}$$

Writing b/a as r, the capital cost may be written :—

$$\text{Capital cost} = \alpha\left[a^2(r^2 - 1) + \beta\frac{r + 1}{r - 1}\right]$$

Differentiating with respect to r and equating to zero gives us :—

$$a^2r = \frac{\beta}{(r - 1)^2}; \quad \text{or} \quad r(r - 1)^2 = \frac{\beta}{a^2}$$

and solving this equation by trial for various assumed

values of β/a^2 we obtain the relation between r and β/a^2 which is plotted in Fig. 2.

Using this curve in conjunction with the formula for capital cost, we can write down at once the cost of an electromagnet the equivalent of the 15 per cent cobalt steel, and one which gives the minimum total capital cost for the different values of the various quantities concerned. Owing, however, to the large number of independent variables involved in the cost of the electromagnet, a slightly different method of comparison has been adopted in order to simplify the graphical work involved.

Consider the cost of the cobalt steel magnet itself. We have seen that the density in the magnet is 5 000 at the point of $(BH)_{max.}$, whereas that in the soft iron is 10 000. The section of the cobalt steel must therefore be equal to twice that of the electromagnet, or, as an alternative, we may take it as the same section but reckon the price per cm³ as doubled.

Turning now to Table 4, we see that for a 15 per cent cobalt steel the total cost for a value of $(BH)_{max.}$ area of 1 000 000 varies between 1·131d. and 1·595d. As the shape of the magnet is probably fairly simple we may be justified in adopting a value somewhat below the mean of these two. Let us therefore adopt the figure of 1·25d.

Referring to Table 2 we see that the volume of the magnet is 1·55 cm³, so that the price becomes $1\cdot25/1\cdot55 = 0\cdot807$d. per cm³. Doubling this to allow for the difference in density we obtain :—

Cost of permanent magnet per cm³ = 1·614d.

The actual cost of the cobalt steel magnet per cm length may therefore be written down as

$$1\cdot614\pi a^2$$

while that of the electromagnet is, as we have seen,

$$\pi p_c\left[a^2(r^2 - 1) + \beta\frac{r+1}{r-1}\right]$$

These are equal when

$$1\cdot614\pi a^2 = \pi p_c\left[a^2(r^2 - 1) + \beta\frac{r+1}{r-1}\right]$$

or when

$$\frac{1\cdot614}{p_c} = r^2 - 1 + \frac{\beta}{a^2}\cdot\frac{r+1}{r-1}$$

In order to avoid drawing a series of curves for different values of β, the right-hand side of the equation has been evaluated and plotted in Fig. 3 against the corresponding value of $a/\sqrt{\beta}$. The points of intersection of this curve with the horizontal lines corresponding to the value of $1\cdot614/p_c$ give the transition points. For values of $a/\sqrt{\beta}$ less than these the cobalt steel magnet is the cheaper, while for values greater than these the electromagnet has the advantage. Since the term a occurs in the form of the fraction $a/\sqrt{\beta}$ we see at once that the area of the core at which a change-over is justified varies directly as β. The flux therefore varies directly as β also.

Clearly then the following features all tend to favour the case of the permanent magnet :—

(1) High cost of copper.
(2) Small size of core, i.e. small working flux.
(3) High value of β, which in turn may be due to :—
  (a) Long working hours (high value of n).
  (b) High cost of power (high value of k).
  (c) Bad space factor (high value of ρ).
  (d) Low rate of interest on capital (low value of p).

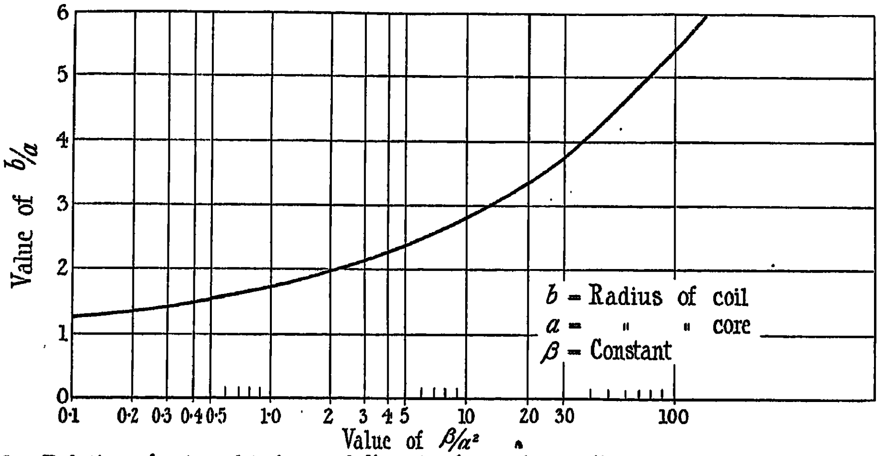

FIG. 2.—Relation of external to internal diameter for various coils of the economical dimensions.

The fact that p_c occurs in the denominator of the quantity β will to some extent balance its effect under (1) above, but as we are concerned with the quantity $\sqrt{\beta}$ its effect will thus be only of secondary importance. The appearance of p_c in the β term is, of course, due to the adjustment which has been made in order to give minimum cost for any given set of conditions, and while this adjustment makes the increase in cost due to rise in value of p_c the least possible, it can never completely offset it.

Examples.—In order to make clear the application of the foregoing formula let us now apply the results obtained to some actual cases, and endeavour to see where the transition points occur in practice.

(1) Let us take first the case of a small, fairly high-voltage, fan motor, or high-voltage generator running for long periods, say 7 000 hours per annum, and using power at a relatively high price of, say, 8d. per unit.

Let us take the copper space factor of the field coil as 25 per cent, giving $\rho = 7 \times 10^{-6}$ approximately.

Take p as 5 per cent, and take the price of copper

+ insulation + charges on winding as 10s. per lb.; $p_c \doteq 0\cdot6$.

This gives us for β the value

$$\frac{100 \times 7 \times 8 \times 104^2 \times 7 \times 10^{-6}}{5 \times 0\cdot6} = 140$$

Fig. 3 shows that the corresponding transition point corresponds to a value of $a/\sqrt{\beta} = 1\cdot8$. Consequently $a = 1\cdot8 \times \sqrt{140} \doteq 21\cdot3$ cm and the corresponding flux would at $B = 10\,000$ be equal to 14 megalines. This is quite a large amount of flux, much larger in fact than corresponds to the small fan motor which we assumed for this example, and would seem to show that for special conditions such as have been chosen, with high energy cost and long working hours, permanent fields might with advantage be employed on quite large machines.

(2) As an opposite extreme let us consider the case

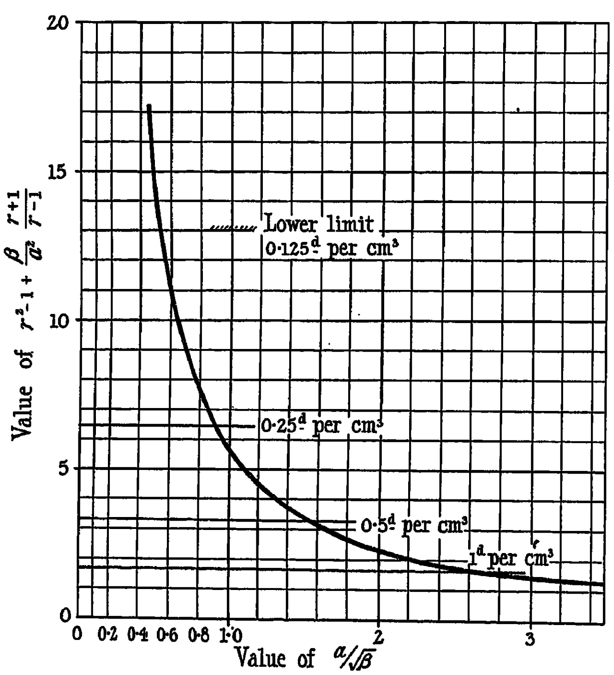

FIG 3.—Determination of transition points where the costs of a permanent magnet and of an electromagnet are equal.

of a piece of apparatus for a fairly low voltage and wound with relatively thick wire. Assume also that the number of hours worked per annum is less, say 2 000, and that power is available at the low rate of 1d. per unit. Take the copper space factor as 40 per cent, and the cost of winding at 1s. 6d. per lb. Then

$$\rho = 4\cdot25 \times 10^{-6} \quad \text{and} \quad p_c = 0\cdot135\text{d. per cm}^3$$

Taking p as before at 5 per cent we obtain:—

$$\beta = \frac{100 \times 2 \times 104^2 \times 4\cdot25 \times 10^{-6}}{5 \times 0\cdot135} = 13\cdot6$$

The point of intersection of the curves on Fig. 2 gives $a/\sqrt{\beta} = 0\cdot59$, so that $a = 2\cdot17$ cm and the corresponding flux at $B = 10\,000$ will be 148 kilolines. Even this amount of flux is considerably more than the working flux of the average small fan, or industrial motor, so that it would seem that under practically all conditions the use of permanent fields for such machines is economically justifiable.

The two foregoing examples will serve to show that even in ordinary small engineering work the use of permanent fields in place of wound ones deserves serious consideration on economic grounds alone, although it will be granted that if first cost alone is to be considered and no allowance made for the capitalized value of the lost energy it is but rarely that the permanent field will show to advantage.

A little consideration will show, too, that in many cases the conditions are much more favourable to the permanent field than in the examples we have chosen. Particularly is this the case where the energy is supplied from primary batteries or small accumulators which only show a low overall efficiency. Examples of these would be portable motor-generators, etc., for wireless work, signalling apparatus, etc., while it would seem that for small petrol generating sets the use of a permanent-field generator might be economically sound. With such a set the fuel cost may easily run as high as 3d. or 4d. per unit, and when to this is added the cost of lubricating oil, etc., it can easily be seen that the transition point will correspond to a generator of some considerable size and that, particularly in the class of a lighting set which runs for long periods and is used with a floating battery of small capacity, the permanent-field machine is worthy of serious consideration. Moreover, the permanent-field machine has the important advantage that its characteristics do not alter as the field winding heats up, so that it is a comparatively simple matter to arrange for the governor to give a constant voltage under all conditions.

4. EXAMPLES OF APPLICATIONS OF COBALT STEEL.

The following examples have been chosen among a number which are available as typical cases of applications which have now been worked out on a commercial scale.

Magnetos.—Cobalt steel magnets as applied to magnetos fall under two headings:—

(i) Applications made without important change of design and on economic grounds only.

(ii) Applications involving radical alterations in design or making designs possible which could not successfully be carried out any other way.

(i) An example of the first of these is given in Fig. 4, which gives sectional views of three magnetos of the same performance, the one employing tungsten steel magnets, and the other two cobalt steel magnets. The actual data for the machines are given in Table 5.

A considerable saving in cost was obtained at the time the change-over was made, but at the present time, owing to the fact that labour costs have dropped more than steel prices, the magnet prices themselves

are slightly higher for the cobalt steel machine. This is, however, offset by the saving in other directions which the simpler and more symmetrical design makes possible, although the difference is only small and would not at the present time justify any firm in changing over from tungsten to cobalt steel.

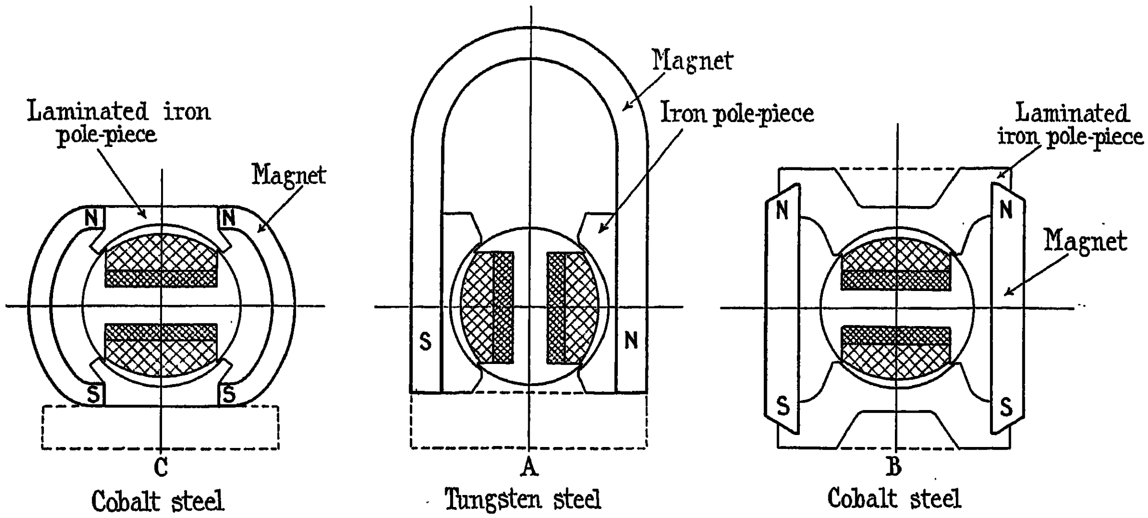

FIG. 4.—Sections of alternative designs of magnetos with tungsten and cobalt steel magnets.

The ordinary magneto, in fact, offers a very good example of a case where a reduction in the price of cobalt steel by about 25 per cent would open up a greatly extended field of use.

TABLE 5.

	Machine C (cobalt steel)	Machine A (tungsten steel)	Machine B (cobalt steel)
Magnet section	$2 \times 55 \times 7 = 7 \cdot 7$ cm^2	70×10 mm $= 7$ cm^2	$2 \times 35 \times 11 = 7 \cdot 7$ cm^2
Magnet length	$7 \cdot 8$ cm	24 cm	$7 \cdot 5$ cm
Magnet volume ..	$60 \cdot 0$ cm^3	167 cm^3	$58 \cdot 0$ cm^3
Material of magnet ..	15 per cent cobalt steel	Tungsten steel	15 per cent cobalt steel
$(BH)_{max.}$	650 000	240 000	650 000
$(BH)_{max.} \times$ volume ..	39×10^6	40×10^6	38×10^6
H at $(BH)_{max.}$ point ..	125	40	125
Available M.M.F. ..	970	1 040	940
B at $(BH)_{max.}$ point ..	5 200	6 000	5 200
Flux at $(BH)_{max.}$ point..	40 kilolines	42 kilolines	40 kilolines

(ii) Under the second category come a number of novel types of magneto, generally of the revolving-magnet type, which have been developed since the advent of cobalt steel. The revolving-magnet type of machine has undoubtedly certain great advantages, particularly as regards mechanical robustness and for aeroplane work, or in cases where the drive is harsh and irregular. A revolving magnet of tungsten steel is, however, very heavy and difficult to accommodate, and its large moment of inertia introduces severe stresses in the shaft and driving gear. The practical development of this type of machine has therefore been rendered possible by the introduction of cobalt steel, although here again the high cost of the material is against the commercial development of this type of magneto for ordinary service.

Fig. 5 gives a sectional drawing of a machine of the revolving-magnet type, designed to give the same electrical performance as the machines illustrated in Fig. 4. Owing, however, to the limitations of space imposed on the magnet, a 35 per cent cobalt steel was adopted, the data of the magnet being as follows :—

Total section	7 cm^2
Length	6 cm
$(BH)_{max.}$	900 000
$(BH)_{max.} \times$ volume	$37 \cdot 8 \times 10^6$
Available flux at $(BH)_{max.}$ point	$39 \cdot 5$ kilolines
Available M.M.F.	960

The adoption of the figure of 900 000 for $(BH)_{max.}$ against the figure of 800 000 quoted in the paper

requires some explanation. It has been adopted for two reasons:—

(1) The magnets are comparatively small in section and it is found that small sections usually give higher figures than larger ones.

(2) These magnets are subjected to a triple heat treatment similar to that already described, which has the effect of slightly increasing the value of $(BH)_{max.}$ even of a 35 per cent steel. Such treatment, while not possibly economically justifiable in the ordinary case, is of value when it is important to get the magnet into the least possible compass.

Small generators.—Generators employing permanent magnets have for a long time been employed for such classes of services as bell-ringing, shot-firing, insulation-testing sets, etc., but not as a rule for the steady generation of any considerable amount of power. Since the introduction of cobalt steel several firms have successfully produced small permanent-magnet direct-current generators for car- and cycle-lighting work. A reduction in cost of material would doubtless result in a very extended application to this class of work.

Further useful extensions of these small machines which may be expected in the future are to small electric lighting sets on the one hand, and to generators for tachometers on the other. A particular instance of the lighting generator which might repay careful study would be in connection with wind motors for battery charging on farms, in country houses, etc. Such a generator, having no field losses, could be made to commence to charge at a very low wind speed, and the average efficiency over periods of varying wind strength would be much higher than for the machine with a wound field.

Used as a tachometer the small generator with cobalt steel magnets would possess many advantages, as, owing to its compactness, it can be very easily housed and could in most cases be driven direct by the shaft whose speed it is required to measure, while

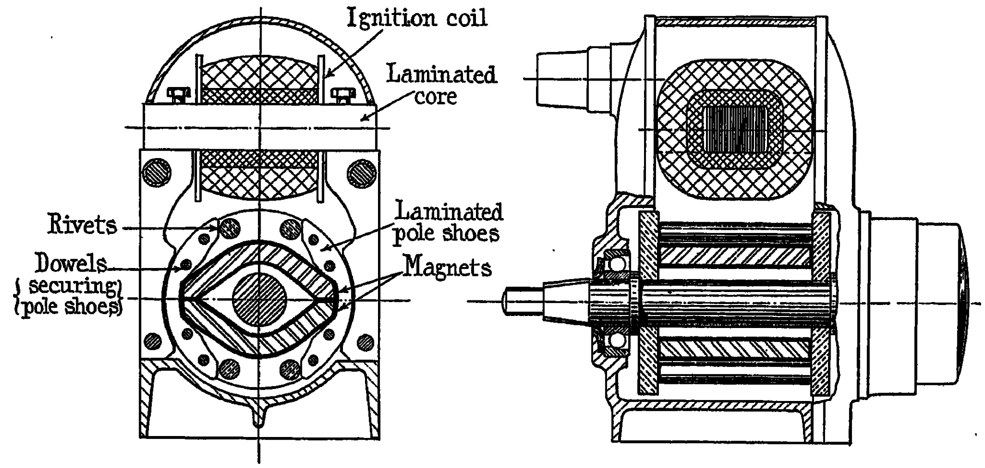

FIG. 5.—Revolving-magnet machine (cobalt steel) designed for same performance as machine illustrated in Fig. 4.

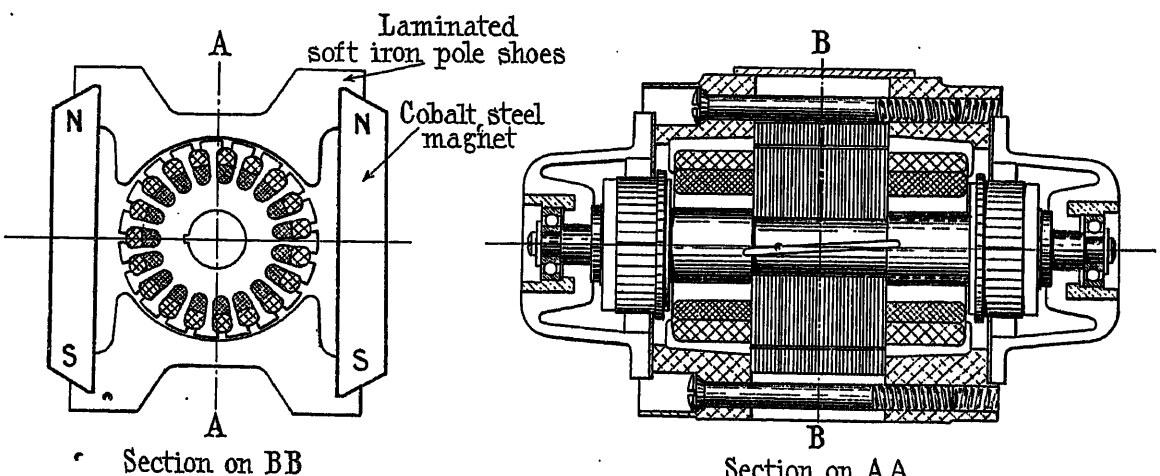

FIG. 6.—Sectional views of small motor-generator with permanent fields. Working flux = 45 kilolines (approx.).

it might clearly form a useful and reliable speed indicator on locomotives of all descriptions.

Motor-generators.—A particular example where permanent fields can be used to advantage is for small

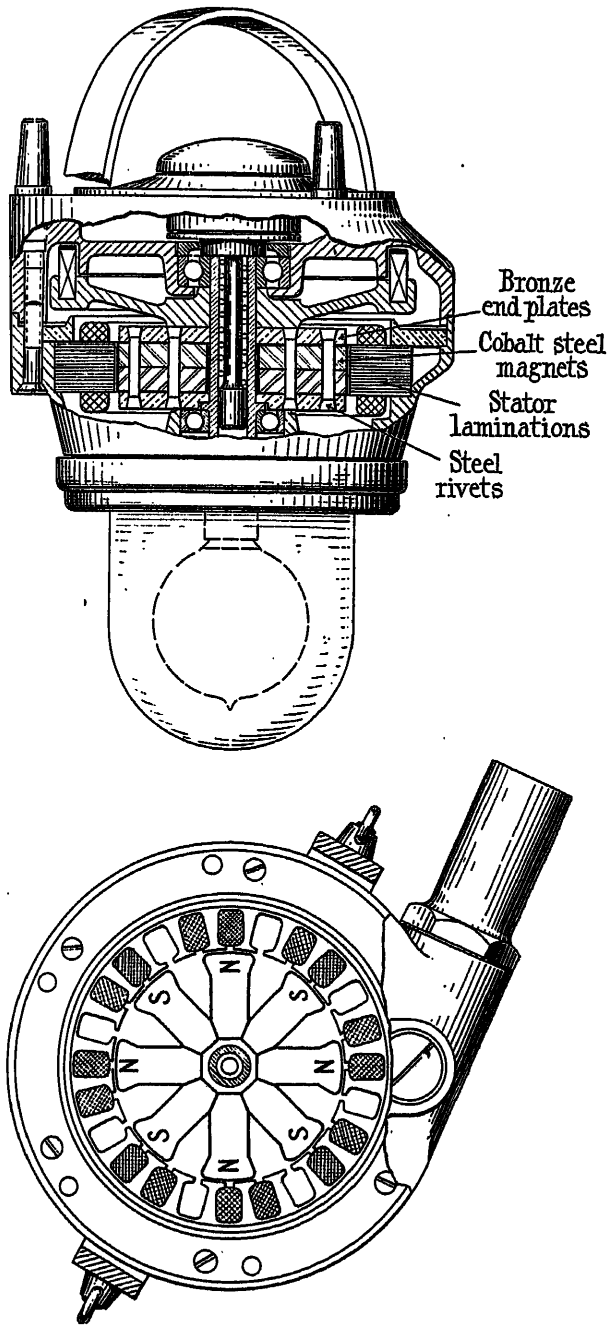

FIG. 7.—Section of air-driven miner's lamp, showing multipolar magnet of cobalt steel.

motor-generators, particularly for wireless work. A number of such machines have been made for supplying the anode voltage for small transmitting sets, receivers and amplifiers. These machines take current at 6 or 12 volts from an ordinary automobile battery, which serves also to provide the filament-heating current, and deliver any required voltage up to 500 on the secondary side. Owing to the use of a permanent field they are light and compact, and the power consumption is remarkably small. For example, a machine giving 120 volts for power-amplifier work takes only 6 watts on the primary side when running light, and of this at least half is accounted for by brush friction. Such a machine has many advantages over the small high-tension battery normally employed, particularly when the voltage and current consumptions are high or where it is to be employed in hot climates. A sectional drawing of such a machine is given in Fig. 6.

Alternators.—While the demand for small alternators in ordinary engineering work is not great, there are certain uses to which such machines are put, and in many cases the cobalt steel magnet will be of very great assistance, particularly where direct current is not available for excitation. Small alternators have been employed for wireless transmission, but at the present time, now that valve transmitters are practically universal, this type of machine is not of importance. They have also been employed on aeroplanes for supplying three-phase current to gyroscopes, and in this case the use of cobalt steel magnets has been found of great assistance in producing a light and compact design. Another special application which may be mentioned is an air-driven miner's lamp, in which the use of a revolving magnet of cobalt steel, driven by a small air turbine, enables a powerful light to be obtained with complete safety from any risk of explosion, even under the worst conditions. Fig. 7 gives a sectional drawing of one of these lamps, and illustrates clearly the mechanically strong and compact construction of the rotor. This construction would be quite impossible were it not for the high coercive force of cobalt steel, which enables the length of the magnets to be kept down to the minimum.

Special apparatus.—There are many applications of cobalt steel magnets apart from the various forms of generators which have just been described, and it is not, of course, possible to enumerate them all. One particular application to which the material has been successfully employed is for polarized cut-outs serving to interrupt the charging circuit of a battery should the dynamo stop or reverse, and there are, of course, many types of polarized relay in which the material might be utilized. Compass needles, again, afford a wide field for the use of steel of magnetic properties superior to those of tungsten or chrome steels. The cost of the material itself is but small, while the gain in pointing power for a magnet of given dimensions and inertia is very considerable.

CONCLUSIONS.

(1) The economy of substitution of a cobalt steel permanent magnet for one of chrome or tungsten steel is dependent upon many factors, and any case requires careful examination on its merits. Generally speaking, the substitution is justifiable where the shape of the magnet is complicated, and where much work must be put upon it, also in those cases where the configuration

of the magnet determines the shape of the apparatus itself, or where extreme compactness or light weight is desired.

(2) The most economical percentage of cobalt would appear to be about 15 per cent, but will depend upon the circumstances involved, the percentage being higher the greater the incidental saving which can be effected by the substitution. The 35 per cent series, while giving optimum magnetic results, is not as a rule economically justifiable at the present price of cobalt.

(3) The price of cobalt is the dominant factor in the situation. A stable price of less than 10s. per lb. would give it a wide sphere of application, while one of 5s. or 6s. per lb. would undoubtedly lead to the complete supercession of chrome and tungsten steels by those of the cobalt series. No widespread adoption can be expected unless there is a reasonable guarantee against exploitation of the supply of metallic cobalt, and reasonable prospect of the price not rising—at all events for some considerable period.

(4) Given the foregoing (stability of price) it would appear that in many instances electromagnets might be advantageously substituted by cobalt steel ones, and that the material might be successfully employed in small generators and d.c. motors up to, at all events, something of the order of 1 or 2 kW rating. This substitution would not in general, however, give a gain in first cost, but only a reduction in losses, which would ultimately repay the extra outlay (if any).

(5) There are a number of special developments which are rendered possible by the properties of cobalt steel and which may lead to its use on a considerable scale, but such developments must of necessity be somewhat slow.

Discussion before the Scottish Centre, at Glasgow, 7 April, 1925.

Prof. G. W. O. Howe: It is somewhat paradoxical that the permanent magnet, which was the first piece of magnetic apparatus ever known, is the piece of magnetic apparatus about which least is known, and the most difficult to design. The average student who could calculate an electromagnet without any difficulty would be quite nonplussed if asked to design a permanent magnet. Another striking fact is that the most common material of construction, viz. iron and steel, is a most complicated material, about which less is known than about almost any other material, and I am sure that everybody will be struck with the complication of the heat treatment described in the paper. One reads on page 823 that the steel is to be preliminarily heated to 1 150° C. in order to break up the complex carbides which are present in the annealed bar, and to ensure thorough solution of the carbides. This is generally followed by a quick annealing at about 750° C. to break up the austenite formed during the previous treatment: the steel is then heated up to 1 000° C. and cooled in air. The metallurgy of steel is truly a very complex business. The importance of permanent magnets is now fully realized. Another thing that must strike anyone reading the paper is the thorough way in which the author has gone not only into the scientific aspect but also into the economic aspect. He is certainly to be congratulated on the very judicial way in which he has inquired into all the pros and cons; he has not unduly boosted the use of cobalt steel but has pointed out both its advantages and its disadvantages. I should like to ask him whether he has had any experience of the permanence of these magnets. It is a very important matter, especially when suggesting the replacement of electromagnets in small motors, to know whether these cobalt steel magnets maintain their magnetism under all conditions.

Mr. A. Brookes: In connection with the question of the use of cobalt-chrome steel for permanent magnets, the problem, in a nutshell, resolves itself into a comparison of the prices of the various available steels. There are really three aspects to the question: (1) The quality of the steel desired; (2) the design of the apparatus involved; and (3) the comparative costs of the various conditions. In regard to (1), I think it might be taken in general that for the majority of electrical apparatus using permanent magnets, chrome steel, although the cheapest, is not of sufficiently high quality for practical requirements, whereas tungsten steel is quite satisfactory except for special cases. In the latter, which are few in comparison, the use of cobalt-chrome steel may be advisable independently of any other considerations; and also in some cases, such as wireless headgear receivers, the question of weight may force manufacturers to use the cobalt steel magnet, even though from other considerations it may not be economical. In regard to (2), in some cases considerable economy might be effected, both in money and in space, by designing the apparatus round the shorter and probably straight cobalt-chrome magnet. In fact, it can almost be stated that, unless this is possible, there is no advantage whatever to be gained by changing from tungsten steel to cobalt-chrome steel except for the special cases cited above. Restricting the problem to the telephone industry, with which I am particularly interested, there is not a single piece of apparatus involving permanent magnets in which, in my opinion, it would be advisable to change over the existing designs involving tungsten magnets so as to bring in cobalt-chrome magnets, with the exception of the headgear receiver referred to above. This statement is only made after very careful investigation into the matter in all its various aspects, and it is an important one from the steel-makers' point of view because the telephone manufacturers are probably the heaviest buyers of magnet steel in the kingdom. In regard to (3), to expand the use of cobalt-chrome magnet steel the cost of such steel in bar form must be appreciably reduced, and unless this be done the further applications of cobalt chrome will, to an appreciable extent, become stagnant. Cobalt-chrome steel has undoubtedly wonderful properties from a technical point of view,

but in practice it largely resolves itself into the higher coercive-force value, which enables the length of the magnet to be reduced to, say, one-third, but does not allow of any reduction in cross-sectional area. In fact, to give the same flux, this should be increased approximately in the ratio of 5 to 4 with a magnetic circuit of small demagnetizing forces. If it be presumed that for most electrical apparatus the tungsten steel permanent magnet (of correct dimensions) gives quite good practical results from a non-ageing standpoint, then the reduced volume is the determining feature as regards (2) and (3). I have had in mind for some time the design of apparatus utilizing revolving cobalt-chrome magnets and pivoted magnets under vibratory stresses, because a useful line is opened here. In many such cases the use of tungsten magnets, under the heavy demagnetizing or vibratory effects, might not give what would be considered to be a practical non-ageing condition. The excessive cost of the 35 per cent cobalt steel compared with that of the 15 per cent steel is to be deplored because of the simpler hardening treatment involved. Possibly further research on the lower-alloy steel will enable the hardening treatment to be simplified. Statistics when dealing with costs involving general conditions can be made to prove almost any desired point, but unless the author can buy to much greater advantage than the quotations I have had from various steel manufacturers, I am inclined to think that the costs quoted in the paper for cobalt-chrome steel are considerably lower than would actually be given in practice, sufficiently so as to upset the conclusions based upon them. I can hardly agree with the statement that "under practically all conditions the tungsten steels show up badly as compared with both their lower- and higher-grade rivals," excepting from the tables quoted. The costs stated for tungsten steels are, in general works practice, appreciably less than those quoted by the author, and, in my opinion, the statement should read as a general conclusion as follows: "Under practically all conditions the low-grade chrome steel is not of sufficiently good quality, whilst the tungsten steel shows up appreciably to advantage over the cobalt-chrome steel unless the design of the apparatus can be sufficiently simplified by the adoption of the latter, or other special circumstances come into play."

Mr. C. H. Wright: Makers of electrical apparatus will welcome the paper, since many cases arise where the ability to use a magnet of the requisite $(BH)_{max.}$ which will go into a small space solves difficulties of construction and opens up a number of possibilities hitherto out of the question. Some 15 years ago I was interested by a suggestion made by a colleague, Mr. E. S. Shoults, to replace the field magnets in a line of fan motors by permanent magnets. The idea was to eliminate troubles with fine-wire field windings in very humid climates and at sea. I went into the question of the size and weight of the permanent magnet and was disappointed. With the new steels the question is quite a different one and distinctly worth consideration. Most of us have had to deal with troubles due to corrosion and humidity effects on fine-wire field windings which often show up on board ship and in humid climates, particularly if the impregnation of these fine windings is not perfect. Such troubles are irritating and sometimes involve a disproportionate expense. What does not exist will not give trouble, and it may prove well in many cases to replace fine-wire wound field-magnets by permanent magnets. I am interested in the making of permanent magnets, my own experience being, however, limited to tungsten steel magnets for electrical measuring instruments. Some 20 years ago the firm with which I was associated decided to make its own instrument magnets, and owing to indifferent results with gas and similar furnaces we built an electrically heated salt-bath furnace, using the molten salt as the resister. The even heating of the magnets in this liquid bath, and the ease of temperature control, had remarkable effects in producing a uniform product and reduced to an extremely small percentage the wastage due to distortion and cracking. Moreover, a batch of magnets could be dealt with much more expeditiously by the salt bath. This bath, I believe, is still in use for the same purpose, and I should be interested to know if the author finds it useful in dealing with the new steels. The possibility of using straight bars with the cobalt steel is very attractive from both the magnet maker's and the constructor's point of view. Quenching with clamps is, in general, awkward. The magnetic stiffness of cobalt steel renders possible constructions of magnetic circuits which are surprising to those accustomed to tungsten steels. For instance, I have used for some three years a little hand-lamp containing a small generator driven by a trigger handle the steel field-magnets of which are only 1 in. long in the flux direction. It is still in use and the magnets do not appear to have weakened at all.

Dr. S. Parker Smith: I should like to have some more information on the substitution of electromagnets by permanent magnets, especially as regards efficiency. When I first had to design motors for desk fans I was astonished to find what a great loss takes place in the field. Only one who has measured or calculated the losses in the exciting circuits of small machines has any idea of their extent. Therefore I think that from that point of view alone it is worth while considering the permanent magnet. At the time I was doing this —some 14 or 15 years ago—I found that it was quite out of the question to use a permanent steel magnet in motors for desk fans and other small loads. Can the author say what is the magnitude of the losses on the pole faces of these hard steel magnets? On the one hand we get rid of the losses in the field coils, but on the other hand it is quite possible that we may get losses in the faces of the poles. With regard to the author's figures of costs, has he taken into account the great wastage in winding these little bobbins? In one instance I remember that the cost of inspection of these small coils was as high as the cost of winding, and the wastage was very large with the fine wires that had to be used. Any method that would get rid of the high cost of winding bobbins of very fine wire would be a great advantage, and these new alloy steels may solve the problem. On the other hand, there is the question of the price of the special steels.

It has to be remembered that when one evolves standard lines which are usually built by the thousand, the total weight of material becomes very considerable; so that one would have to be assured of his supplies of that material before introducing standardization. In conclusion I should like to ask the author how uniform are these steels.

Mr. J. F. Kayser: As the author has indicated, the high cost of magnet steels containing cobalt has undoubtedly prevented their adoption to a very great extent. I really think that their adoption has been still further prevented by the remarkable ignorance of the majority of magnet users concerning the elements of magnetic circuit design. When the author asked me in 1919 if my firm would be prepared to undertake experimental work on high-coercivity cobalt steels and told us of the advantages they would possess, we made inquiries of some half a dozen of the leading electrical concerns in this country and, without exception, they informed us that a cobalt steel would be useless, as ordinary tungsten steel magnets, with a coercive force of 60, were quite permanent enough. The utilization of permanent magnets during the past five years, particularly that resulting from the author's personal work, has shown their attitude to have been quite wrong. It is unfortunate that, in many cases, the choice of a magnet steel is left largely in the hands of a purchasing agent with little or no technical knowledge, and, in many cases, it is quite impossible to get beyond him. If we consider a machine using a tungsten steel permanent magnet, there are three possibilities: (1) The tungsten steel magnet is working economically; (2) it is working too near to the remanence point; and (3) it is working too near to the coercive-force point. In cases (1) and (2) the replacement of the tungsten steel magnet by a high-coercivity cobalt steel magnet will, in every case, lead to a lessening in efficiency, and the instrument must be re-designed to suit the properties of the new steels. In case (3), however, a greater efficiency can, in every case, be obtained by simply substituting the tungsten steel magnet by an exactly similar magnet made from cobalt magnet steel. The loud-speaker is a well-known example of the last. Some few years ago tungsten steel magnets were used, but now practically every loud-speaker on the market is fitted with a cobalt steel magnet.

Mr. E. A. Watson (*in reply*): I quite agree with Prof. Howe as to the general lack of knowledge in regard to permanent magnets, not only as regards the relationship between the magnetic properties of the steel itself, but also as regards the principles underlying the application of permanent magnets and the design of apparatus in which these are incorporated. It is certainly a subject which has been very much neglected in the past, and one to which a great deal more attention might profitably be given; but what I should like to emphasize more than anything else is the importance which attaches to a proper co-ordination between the engineer and the metallurgist. In the past this has been entirely lacking: the engineer, as is confirmed by Prof. Howe's remarks, has a very scanty knowledge of the metallurgy of steel and the various transformations which take place when a piece of magnet steel is hardened, while the metallurgist, on the other hand, has only the vaguest ideas as to magnetic properties and their ultimate meaning. If we are to get any real progress in the improvement of permanent magnets, it will be necessary for the work to be carried out by men who combine both branches of knowledge and who are able to co-ordinate changes in the magnetic properties with the corresponding changes in the metallurgical structure of the steel itself. It is, perhaps, not fully realized that magnetic analysis shows that in the majority of permanent magnets not more than 75 to 80 per cent of the iron can be accounted for as being in the magnetic state, and it is quite likely that well-directed research will find some manner of accounting for at least a considerable proportion of the iron which appears to be present in the non-magnetic condition. At all events a very promising avenue of research work is opened up in this direction—one which has been very little explored and which offers possibilities of making really useful contributions, not only to our knowledge of the materials, but also to their application to the needs of the engineer.

As regards the permanence of these magnets, the whole subject of permanence is one which requires careful research and on which very little really definite is known. Many experiments have been made on the so-called permanence of magnets, but in the majority of cases no proper steps have been taken to discriminate between the many different factors which may cause loss of magnetic power. Quite recently Mr. Evershed has shown * that apart from the ageing due to vibration and temperature changes, there is a further ageing which occurs due to gradual degradation of the steel, and any real work on permanence must separate these two factors before the results can be of real utility. As regards the degradation of the steel, very rough experiments which I have carried out on the air-hardening cobalt-chrome series of steels seem to show that this degradation is very much less pronounced than in the case of a water-hardening tungsten steel, and my own theory is that in any steel—of an air-hardening type—in which the hardening molecule is relatively immobile, degradation due to ageing will be less pronounced than in a water-hardening steel, in which the hardening molecule can move more freely, but I am afraid that at present this is only a conjecture which requires a considerable amount of research before definite statements can be made. My own experience, based in a practical way on the application of cobalt steel magnets for about five years, is that under the same conditions they are at least as permanent as tungsten steels. My firm has had experience of these magnets not only for magnetos, but for small generators, motors and other special classes of apparatus, and we have never had any cases of trouble due to ageing of the magnets, or loss of flux, which could not be accounted for by ill-usage or accidental demagnetization by an external source.

In reply to Mr. Brookes, I am afraid that I cannot agree with his conclusions regarding the relative merits

* See page 725.

of tungsten and chrome steels. I quite agree with him that if a piece of apparatus has been designed for a tungsten steel magnet the direct substitution of chrome steel for tungsten steel, without any change in dimensions, might lead him into difficulties through what he would term "the inferior quality of the steel," but if the slightly lower magnetic values of the chrome steel are recognized and due allowance made for these in proportioning the magnets, I see no reason at all why chrome steel should not give results quite as satisfactory, and I believe that a certain saving in cost might accrue. It is certainly significant that chrome steels should be used so largely in the United States, although I agree that this may be, in part, due to difficulties which have at times occurred in that country in obtaining the requisite supplies of tungsten.

As regards Mr. Brookes's comparison between cobalt and tungsten steels, I think that really we are in agreement, as I would certainly never suggest that a cobalt steel can show any saving, unless the apparatus can be designed around it and advantage taken of the simplification in design due to the shorter length of magnet which can be obtained. In our own case, for instance, although in changing from tungsten to cobalt steel we actually increased the cost of the magnets slightly, the incidental savings obtained and, in particular, the economies in connection with the labour of machining and assembly, were quite sufficient to outweigh the increase in cost due to the change in material. The costs given in the paper for cobalt steel were, as stated, not based on market quotations but on an estimate of what the steels could be produced for under certain conditions, and although at the time the paper was written market quotations were considerably above these figures, at the present time they are substantially in agreement, some prices ruling slightly above the figures and some below. I am pleased to hear that Mr. Brookes reports for the working of tungsten steel considerably lower costs than are quoted in the paper, and I think that if the same good practice were applied to cobalt steels a similar reduction could be expected in this case also, so that this should not affect the comparison to a very great extent.

I am pleased to have Mr. Wright's views, and also those of Dr. Parker Smith, that there is a field for small permanent-magnet motors. They should certainly be more reliable, and the smaller sizes, at all events, should probably be cheaper, even in first cost, than machines with wound field-magnets. There is no difficulty whatever involved in their manufacture, and it should be a line well worth following up. Motors with permanent fields would have the peculiarity that the direction of rotation could be reversed from a distance by merely reversing the polarity of the supply. This might, of course, in certain cases be disadvantageous, as for instance with portable motors, or fans fed through a plug and socket, as care would have to be taken when inserting the plug to ensure that the motor would run in the correct direction. On the other hand, there are many cases in which this would be a distinct advantage, particularly for motors operating a remote-control mechanism, signalling devices, etc.

The use of a salt bath for hardening magnets has considerable possibilities, as it enables quick heating to be obtained, together with a very close control of the temperature. Electrically-heated salt baths are, however, very expensive in first cost, and the cost of upkeep of the bath itself is generally considerable. Modern regenerative gas furnaces are fairly cheap to install and give a reasonable efficiency and very uniform heating. Both types of furnace have, in my experience, been tried for cobalt-chrome magnets, but the gas furnace seems at present to be favoured.

I quite agree with Dr. Parker Smith as to the relative improvement in regard to field losses in smaller machines, as the field losses increase rapidly in proportion as the size of the machine is decreased. With permanent-field machines it is possible to get extremely low no-load losses, and extremely good efficiencies right down to the smallest size. I would instance the case of a small 500-volt motor-generator which we are now making and which will run at 4 000 r.p.m. with a no-load loss of less than 10 watts, a figure which can certainly not be obtained with any wound-field machine. The absence of field loss not only increases the efficiency, but also increases the permissible rating of the machine, in that the heating for a given armature loss is substantially reduced. There might, of course, be losses in these machines if solid pole-shoes were employed, but in all the machines which are described the pole-shoes are made of soft-iron laminations, and in any case the use of magnet steel for a pole-shoe is bad practice and, as far as I know, is never adopted. As regards the allowance for wastage and inspection on the fine-wire coils a certain allowance has been made for this by taking a high value of the copper cost for small gauges of wire, but I could not say for certain whether this would be sufficient to cover the case which Dr. Parker Smith has instanced. I quite agree as to the necessity before making any radical change of ensuring that there would be a continuity of supplies of material, but I think that these steels have now been produced for a sufficient length of time for their supply to become fairly well established, and I believe that there is not likely to be any shortage in raw material for a very long while to come, unless the demand should increase to a very great extent indeed. As regards uniformity, these steels, when made by a reputable maker, are really very uniform indeed, and our records, extending over very nearly 5 years (equal to nearly half a million magnets) show that there has been extremely little variation and an almost entire absence of rejection of material for magnetic defects.

In reply to Mr. Kayser, I too was very much struck with the conservatism of manufacturers and users when these steels were first brought to their attention, and with the ignorance of large users in regard to the principles governing the use of permanent magnets. I am afraid, however, that this was no worse than the conservatism shown by the steelmakers when it was first suggested to them that they should attempt to make cobalt magnet steel; and if it had not been for the enterprise of two firms, of which Mr. Kayser's

was one, the development of cobalt steels in this country might have been delayed for an almost indefinite period. As Mr. Kayser points out, apparatus for the use of cobalt steels must be designed to that end, and the direct substitution of cobalt steel for tungsten steel may, in certain cases, even lead to a worse performance instead of a better. There are, however, cases where the tungsten steel is working disadvantageously and under conditions of excessive demagnetization, and in these cases the substitution will lead to a greater improvement than that corresponding to the properties of the material alone.

ELECTRICITY IN AGRICULTURE.

REPORT OF THE ELECTRICITY IN AGRICULTURE COMMITTEE TO THE COUNCIL.

The Committee was appointed by the Council on the 15th March, 1923, for the purpose of reporting on the following points :—

(*a*) Whether there are any special features in connection with the supply and use of electricity in agriculture which need special attention from the Institution by way of education or propaganda, and, if so, what action the Committee recommend the Council to take.

(*b*) And, for the purpose of making a recommendation :—

(i) To investigate and report upon the actual or probable load factor and annual consumption of farms in this country and elsewhere, and on the capital cost to supply authorities of supply to farms, and to farmers of the machinery for utilizing the supply, and of the economic results likely to be obtained by supply authorities and farmers ;

(ii) To report on the desirability of a permanent Sectional Committee of the Institution for dealing with this question.

The constitution of the Committee is as follows :—

Ll. B. Atkinson (*Chairman*).

C. T. Allan. J. F. Crowley.
J. W. Beauchamp. J. H. Edwards.
S. E. Britton. B. M. Jenkin.
W. R. Cooper. R. Borlase Matthews.
F. A. Sclater.

The Committee has held 5 meetings, one of which was at the farm of Mr. Borlase Matthews, Greater Felcourt, East Grinstead. The Committee have collected from various sources a large amount of information as to the work which has been carried out and the results that have been obtained therefrom, with a view to summarizing these results in the form of a report under the following headings :—

A. Uses to which electricity can be put in agriculture.

(*a*) Electric lighting .. In the house, barn, dairy, poultry house, and other buildings.

(*b*) Motive power .. In the house, barn and dairy, and for water pumping and drainage.
In the field.
The amount likely to be used, the consumption per acre of farm lands.

(*c*) Crop stimulation .. The position.
The amount of electricity likely to be used.

B. Capital Outlay.

(*a*) At the farm .. .. The price at which it will pay the farm to use it.
The financial return on this to the farmer.
The method of providing this outlay.

(*b*) On distribution .. The return on this.
The method of providing this outlay.

C. Existing schemes in operation.

The results.
Lessons therefrom.

D. Steps which might be taken by the Institution.

A. Uses to which Electricity can be put in Agriculture.

(*a*) electric lighting.

Electric light is of considerable assistance to the farmer for the lighting of homesteads, farm yards, poultry houses, and buildings, and particularly for the lighting of farm yards during such operations as threshing. Its use permits the carrying out of certain operations by artificial light which can at present be carried out by

daylight only. The risk of fire, always a serious risk on the farm, is minimized where electricity is employed.

(*b*) MOTIVE POWER.

In the house and barn and dairy; pumping and drainage.—The usual applications of electric motors in agriculture are in the house, barn and dairy. In the former case the motors are generally stationary, either attached to the machines they operate, such as chaff-cutting and corn-grinding machinery, or driving by means of shafting a group of machines, as in dairies. Special types of portable motors suited to farm work have been evolved, particularly on the Continent; these are fitted with suitable reduction gearing for the operation of portable machines and of stationary machines which run too intermittently to justify separate motors.

Table 1 may be taken to be a reasonable estimate of use for an average farm :—

TABLE 1.

Consumption of electricity on a farm of 150 *acres.*

	Kilowatt-hours per annum
Lighting (house)	100
,, (buildings)	150
Motive power, barn and dairy ..	1 500
Heating and cooking	1 500
	3 250

It is useful to consider the consumption of electricity on farms in terms of the annual use in kilowatt-hours (or units) per acre. Table 2 sets out the ascertained figures of use on a number of British farms in a certain supply area.

TABLE 2.

Annual use on 33 *farms in a certain supply area in Great Britain.*

Motors on each farm, average ..	1·4	
Average horse-power	10	
Electric lamps per farm house ..	18	
Electric lamps in buildings ..	18	
Average consumption per annum :—		
Lighting	370	units
Heating	470	units
Power	1 370	units
Average total consumption per annum	2 210	units
Average acreage	230	
Average consumption per acre per annum	9·5	units

Statistics of use on Continental farms which have used an electric supply for several years show a higher consumption than this, averaging 22 units per acre.*

The consumption of electricity per acre of arable land is apparently a function of the fertility of the soil.

* See N. EKWALL: "Electricity in Agriculture," *Transactions of the First World Power Conference*, vol. 4, p. 571; F. A. GABY: "Electrical Service for Rural Districts as provided by the Hydro-Electric Commission of Ontario," ibid., p. 23; F. H. KREBS: "Technical Development and Financial Organization, including Co-operative Schemes for Electricity Supply in Agriculture in Denmark," ibid., p. 242; and R. BORLASE MATTHEWS: "Electro-Farming Economics," ibid., p. 539.

In a very fertile region in the North-East of Germany the consumption averages (without any electric ploughing) 100 units per acre.*

In accordance with the returns for 34 rural districts in Germany, the consumption per acre was 12·5 to 22·5 units for lighting and 27·5 to 42 units for power, a total of 40 to 65·5, or an average of 50 units per acre.†

In the field.—The principal potential use of electric motors is for ploughing, harrowing, etc., and for threshing.

Ploughing.—The application of electricity to ploughing requires motors of from 12 to 125 h.p.,* and is carried out in one of several ways :—

(*a*) By means of electric tractors, fed by a flexible cable carried from a movable pole, which are propelled across the field in a similar manner to petrol or steam tractors.

(*b*) By means of electric tractors propelled by engagement with a chain, which is preferably laid across the field to be ploughed and which is moved forward after each operation.

(*c*) By means of two stationary motors placed one at each side of the field to be ploughed, with a single steel cable traversing the distance between them, the plough being hauled in one direction by one motor and in the other direction by the other motor.

(*d*) By means of a single movable motor placed at one side of the field and a movable anchored pulley at the other, the plough being moved from one side of the field to the other by a steel cable which passes from cable drums on the motor round the pulley.

(*e*) By the Howard or Fisken system, where a single fixed motor is used and, by means of ropes with movable anchored pulleys, the plough or other implement is drawn backwards and forwards on the field.

Systems (*c*) and (*e*) are those which have been most generally adopted. In general these systems of ploughing, as in the case of steam-ploughing on the well-known Fowler system, are applicable to large farms or suitable for employment by contractors who carry out the work on terms for the individual farmer. The problem of electric ploughing, although it is one of the most important on the farm, particularly in view of the growing importance of the sugar-beet industry which requires deep ploughing, cannot be said to be fully solved. It would be the most important load on the farm from the point of view of the power supply engineer. All the arable land on a farm might well be ploughed twice a year, with a consumption of at least 20 units per acre, that is, 40 units per acre per year. Cultivation work on similar lines would take about half this amount, say 20 units per acre, or a total of 60 units per acre; that is, on a farm of 150 acres, half arable, 4 500 units for the field operations alone.

In the absence of any extended experience of electric ploughing in this country comparative costs are not available.

* R. BORLASE MATTHEWS: "Electro-Farming, or the Application of Electricity to Agriculture," *Journal I.E.E.*, 1922, vol. 60, p. 736.

† *Elektrotechnische Zeitschrift*, 1923, vol. 44, p. 633, and *Electrical World*, 1923, vol. 82, p. 125.

The following British figures of cost of other methods may be noted as generally accepted :—

CONTRACT PRICES.

Steam ploughing.—15s. to 25s. per acre, at about 6 in. deep.

Tractor ploughing.—17s. 6d. to 30s. per acre, but this machine is hardly capable of ploughing deep enough on the heavy land without materially adding to the weight of the engine, which is detrimental to corn-producing, as it is apt to make a " pan " which the water cannot penetrate and, consequently, the land is kept in a wet condition very injurious to plant life.

Mole draining.—15s. to 30s. per acre, but varies very much in different parts of the country. In Northamptonshire the drains are made from 5 to 7 yards apart, and in some cases up to 9 or 10 yards. The 7 yards is a good average at from 1 ft. 6 in. to 2 ft. 3 in. in depth. In Essex the drains are very often only 4 yards apart.

Horse ploughing.—20s. to 35s. per acre, according to the nature of the land.

COST OF ELECTRIC PLOUGHING.

The following information has been obtained * as to the price at which electric ploughing is done in France by contract. It will be understood that this represents cost and profit, the price being regulated by competition with horse ploughing.

The figures are given subject to a caution that comparison between the British and French figures must not be taken too literally, as the external and internal values of the franc are very different.

TABLE 3.

Contractors' Price List.

Depth of		Total depth	Price per acre	
Ploughing	Subsoiling			
in.	in.	in.	francs	s. d.†
10–12	5–6	15–18	137	34 3
8–10	5–6	13–16	130	32 6
12–14	—	12–14	127	32
10–12	—	10–12	120	30
6–8	5–6	11–14	120	30
8–10	—	8–10	93	23
6–8	—	6–8	66	16 6

† At 80 francs to the £.

The charge for scuffling to a depth of about 4 inches was 40 fr. (say 10s.) per acre.

In France it is usually reckoned that 10 francs (say 2s. 6d.) per 4 inches of depth is a reasonable charge to pay to contractors for ploughing and subsoiling.

In the 1924 season an electric ploughing set ploughed 1 453 acres (588 hectares). Scuffling was done at the rate of 49½ acres (20 hectares) per day; while a six-furrow plough accomplished 16¾ to 19¾ acres (6 to 8 hectares) in the same time, and a four-furrow deep plough did 12½ acres (5 hectares).

Threshing.—Threshing by means of portable electric motors is another operation which is frequently done on the Continent through contracting firms, who supply a portable transformer for connecting to the distribution system, a cable drum and the necessary large portable motor.

(*c*) CROP STIMULATION.

A good deal of isolated and badly co-ordinated experimental work has been done by various observers as to the stimulation of field crops, from which a general impression only can be received ; it would appear, however, to be established that it is possible in certain cases to increase considerably the quantity and quality of certain crops.

In 1918 a Committee was formed by the Government under Sir John Snell to investigate and report on this question, and under its guidance seven reports * have been prepared covering an examination of the work already done and reporting on experiments both in the field and on plants under pot culture. The results of the field experiments were so conflicting and difficult to reconcile that it has been decided at present to concentrate on pot-culture experiments, with a view to determining as quickly as possible the general conditions of electrification which are favourable, after which field operations will be resumed.

It has been stated in the second Report of the Committee referred to, that increase in yield averaging about 30 per cent had been obtained in field experiments.

The matter has reached a stage which is as yet of no very great practical importance or direct application owing to lack of commercial data and apparatus suitable for placing in the hands of the farmer.

The amount of electricity used for the purpose is insignificant, not amounting to more than about 10 watts per acre, applied for, say, 2 hours a day for one to two months of the growing period.

B. CAPITAL OUTLAY.

(*a*) *At the farm*.—This depends of course on whether the installation at any particular farm is for the purpose of field operations or for lighting, barn and dairy use. Speaking generally, it is probable that as regards the larger field operations the capital outlay is so considerable relative to the amount of use on any particular farm, that except in the case of the largest farms the ploughing and cultivating tackle, as has occurred in the case of steam tackle, will be owned by contractors who will do the work for the farmer. On the other hand, the use of electricity in the house, barn and dairy will be made with machinery and appliances provided by the farmer and the cost may be estimated as follows :—

	£
3 electric motors aggregating 10 h.p., with starting gear and reducing gear ..	60
Electric light, 36 points in house and building	36
Sundry cable and switchgear not included in the lighting	20
	116
Sundry household apparatus	40
	£156

* By the courtesy of M. Hubert, 44, Rue du Louvre, Paris, who ascertained the figures from Les Grands Secteurs Electriques, Versailles.

* Copies may be obtained from the Ministry of Agriculture, 10, Whitehall-place, London, S.W.

Price of electricity obtainable.—As to the price at which it will pay the farmer to use it, there is evidence that farmers will willingly pay for lighting 8d. per unit, for heat 2d., and for power 4d. (electric ploughing from 1d. to 2d.).

Financial return to the farmer.—It is difficult to put any precise figure on the financial return to the farmer. It is probable that on farms employing five men and upwards where other power has not been installed, at least one man can be saved. On smaller farms the advantage would be rather in reducing the number of hours the farmer and his family would have to work and reducing the actual manual toil involved, by reducing risks of fire, or increasing the output of the farm. There is no doubt also that the provision of good lighting in the mornings and evenings of the winter months contributes to saving of waste of materials and of time lost. In the case of farmers owning a considerable head of poultry, it has been established that by lighting the poultry houses in the winter months morning and evening there is an improvement in the average value of the eggs produced, not so much in an increased total number as in their distribution towards the months when daylight is shortest, with a consequent advantage of about 20 per cent in their average value. The result of these various factors is that in the case of an ordinary farm it is estimated by the Committee that these outlays will repay themselves in about four years, after which there will be a return, allowing for repairs, of probably 20 per cent per annum on the money spent on the equipment.

Although this is attractive, the fact has to be faced that farmers have lost a large amount of their capital during the last few years, and that it is probable that in the majority of cases some system of furnishing the equipment on hire-purchase terms would be necessary to encourage the adoption of electricity.

(*b*) *On distribution.*—In this question lies the principal problem of the supply of electricity for agricultural purposes. Whatever the future may hold, there is universal agreement that, in the early stages of establishing a supply network to supply purely agricultural areas with electric power, there will not be a load which will produce a fair return on the expenditure for distributing mains if the development of the uses of electricity is left almost entirely to the initiative of the farmers. The experience in England, France, Italy, Switzerland, Holland, Sweden and Canada leads to the same conclusion and to the general statement that (1) there must exist other sources of income for the transmission system capable of carrying a large, if not the major, part of the capital charges on the investment during the period required for the natural education of the farmers; or (2) there must be an abnormal economic demand for the energy, rendering possible its sale at an abnormal price; or (3) there must exist an abnormal supply of electrical energy which could not otherwise be sold, rendering economic its sale at a price well below the average cost of production, or (4) there must exist social or political reasons why the supply should be furnished at an uneconomic price on account of other advantages to be gained.

In the first category we have such cases as exist in Sweden, where the transmission lines from the waterfalls pass along the valleys in which the agricultural areas are situated, and the lines are easily tapped. In Holland we have the case where lines are put up for distribution to towns and for the purpose of drainage pumps throughout the country, which lines are again easily tapped for agricultural purposes. Or again in Switzerland, where we have a large number of small towns in which are situated semi-domestic industries which in fact are bearing the costs of the transmission and distribution networks used for agricultural purposes.

In the second category we have France, where the shortage of man power stresses the necessity for the supply of motive power and where, in addition, the necessity of maintaining a source of military strength necessitates the maintaining of the agricultural areas at their highest working power and making them as attractive as possible to the population, even at the expense of the State.

The third case is illustrated by Italy, where there is a superabundance of hydraulic power from the Alps in the summer time, the season of the year when the industrial demand is at its lowest and the farming demand at its maximum.

In this country it is probable that the first mentioned consideration will be the predominating influence, though it is likely that the existence of loads other than those provided by agricultural operations or, alternatively, the establishment of industries providing such loads, will be dominant factors so far as rural electric supply is concerned. We find also that in other countries, notably in Scandinavia, Canada and Italy, financial assistance is given by the State towards the provision of rural distribution lines.

C. Existing Schemes in Operation.

In some parts of the Continent the supply of electricity is remunerative. On the other hand, there are many districts where the engineers have not specialized on the rural problem, and these districts are usually unremunerative to the electric supply undertaking. As the farmers become acquainted with the varied uses of electricity, it seems likely that these at present unremunerative districts may become profitable.

When the electrical equipment of railways becomes an accomplished fact there will be a general distribution system in existence which will enable electricity to be carried more widely into the agricultural areas, based upon these main-line transmissions. For the present more tentative methods will have to be adopted; and these for the most part will lie in the direction of extensions from existing plants in towns of moderate size lying within the agricultural districts and where the supply of electric power from such towns will stimulate more intensive methods of farming in the near neighbourhood of such towns and railway systems. Already developments are taking place in this direction. The towns of Altrincham, Aylesbury, Chester, Hereford, Wolverhampton, etc., have already extended or decided to extend their lines into the districts surrounding, while the power supply undertakings in South Wales, Fife, Kilmarnock, etc., are already supplying a number of farmers.

With regard to the actual cost of such distributions, in the cases which have so far been carried out this appears to be higher than a more extended study of the subject will probably suggest. For 6 600-volt overhead bare lines on insulators with creosoted poles carrying three conductors, each No. 10 S.W.G., all to comply with the Electricity Commissioners' Regulations, the cost would lie between £500 and £600 per mile, and it is probable that cheap underground cable systems could be laid in the open country for about the same figure, but the fact remains that the lines erected in agricultural districts in foreign countries have cost much less than this—even as low as £100 per mile in Sweden—and it is probable that a study of the best methods of erecting such lines will lead to a figure of £250 to £500 per mile to comply with the Regulations necessary in this country. A good deal of discussion has taken place as to whether the lines to individual farms should be single-phase or three-phase, and there is little doubt that as regards the lines the single-phase system is cheaper and there is some simplification in transforming and switching gear. On the other hand, the motors are rather larger and more costly and, so far, whatever installations have been completed have been upon the three-phase system.

In order to summarize this part of the Report, it may be well to give the following actual example (in Sweden) obtained by a member of the Committee where conditions were not favourable to a large consumption per acre, as the land was poor. In a rural area of 3 700 acres (of which 1 700 were woodland and waste) about 15 miles of distributors were used to supply 22 farms and 29 other rural customers whose consumption, averaged over several years, was 82 000 units per annum. The return on the capital expended (which was heavy, as the work was carried out during the war) was 5 per cent per annum. The consumption per acre was 22 units, or 5 570 units per mile of distributor. *

D. Steps which might be taken by the Institution.

Although the actual consumption per acre or per farm appears small, yet the total acreage of farm lands in this country is large, being nearly 27 million acres out of the total area of 56 788 366 acres in England, Scotland and Wales, and the supply of electricity to farms, if carried out, would aggregate a very large total, say, under English conditions, 260 million units per annum without electric ploughing or cultivation, and from two to three times this amount if electric ploughing and cultivation as in Continental practice were adopted.

The laying out of the work, the construction of the generating plant and cables or overhead lines, and the supply of plant and accessories would form a very important addition to the activities of the electrical industry. This, added to the social and economic betterment arising therefrom, is of such importance that it is recommended that the Institution should use its influence in promoting this object.

To this end the following are some of the steps that might be taken :—

(1) The appointment of a permanent Committee, to advise the Council of any development arising which they should take note of, or on which they should take action.

(2) The presentation of a memorandum to the Government pointing out the advantages that would arise from a wide distribution of electricity to agricultural counties, and that this should be taken into consideration in fostering schemes of railway electrification.

(3) That a special recommendation should be made to the Government in connection with the provision of financial assistance, either in the form of direct grants or the provision of finance at specially low rates and repayable over long periods, towards the cost of provision of distribution lines in rural areas in districts where there is a prospect of the undertaking becoming profitable in the course of a few years, so as to enable a cheap supply of electricity to be provided for these areas.

(4) That the Institution should take steps to encourage the design by the leading British manufacturing firms of electrical apparatus especially suited to agricultural conditions, such as portable transformers, portable motors for general use, cable reels for enabling temporary connections to be made to such motors, electric ploughing equipments of suitable type, etc.

(5) That in connection therewith the Government should be urged to issue through the Ministry of Agriculture in conjunction with the Electricity Commissioners authoritative leaflets on the subject, showing what has been done and what can and ought to be done by farmers when a supply is available.

(6) That the Institution should offer to co-operate with the Royal Agricultural Society and other agricultural bodies in tests and experimental work, and in formulating a policy for the supply of electricity to the farming population.

(7) That the Institution should take steps to obtain a paper each year on a subject dealing with the applications of electricity to agriculture, and that joint meetings with the Royal Agricultural Society or with one of the other farmers' organizations should be arranged.

(8) That the Institution should take steps to initiate experimental work by or through existing bodies :—

- (*a*) In improving the efficiency of farm implements and machines by redesign of the implements or machines to use the new forms of power available.
- (*b*) In improving the efficiency of methods of crop treatment by means of the new form of power available.
- (*c*) In carrying out investigations that would provide useful data in relation to the application of electricity to agriculture.

(9) That the Institution should take steps to propose Rules for rural distribution networks, overhead and underground. These Rules only to apply to distribution to farms, villages and small industries, leaving other work to be carried out under the existing Regulations as at present approved by the Electricity Commissioners.

INSTITUTION NOTES.

Council for the Year 1925–1926.

The scrutineers (Messrs. J. Coxon, P. Dunsheath and W. L. Wreford), appointed at the Ordinary Meeting held on the 23rd April, 1925, in connection with the ballot to fill the vacancies which will occur in the Council on the 30th September next, have reported to the President that 1 428 ballot papers were returned, of which 28 were spoiled, and that the result of the ballot is as follows :—

President: Mr. R. A. Chattock.

Vice-Presidents: Lieut.-Col. K. Edgcumbe, R.E. (T.A.), and Prof. W. M. Thornton, O.B.E., D.Sc.

Hon. Treasurer: Mr. P. D. Tuckett.

Ordinary Members of Council: (Members) Prof. C. L. Fortescue, O.B.E., M.A., Mr. R. W. Paul, Mr. C. Rodgers, O.B.E., B.Sc., and Mr. S. J. Watson; (Associate Members) Mr. R. Grierson, Major E. O. Henrici, R.E. (ret.), and Mr. J. W. T. Walsh, M.A., M.Sc.; (Associate) Mr. E. Leete.

The Council for the year 1925–1926 will therefore be constituted as follows :—

President.

R. A. Chattock.

Past-Presidents.

A. Siemens.
Col. R. E. Crompton, C.B.
Sir Henry Mance, LL.D., C.I.E.
J. Swinburne, F.R.S.
Sir R. T. Glazebrook, K.C.B., D.Sc., F.R.S.
W. M. Mordey.
S. Z. de Ferranti, D.Sc.
Sir John Snell, G.B.E.
C. P. Sparks, C.B.E.
R. T. Smith.
Ll. B. Atkinson.
J. S. Highfield.
F. Gill, O.B.E.
A. Russell, M.A., D.Sc., LL.D., F.R.S.
W. B. Woodhouse.

Vice-Presidents.

Sir James Devonshire, K.B.E.
Lieut.-Col. K. Edgcumbe, R.E. (T.A.).
A. Page.
Prof. W. M. Thornton, O.B.E., D.Sc.

Honorary Treasurer.

P. D. Tuckett.

Ordinary Members of Council.

Captain J. M. Donaldson, M.C.
The Viscount Falmouth.
Prof. C. L. Fortescue, O.B.E., M.A.
R. Grierson.
Major E. O. Henrici, R.E. (ret.).
W. E. Highfield.
Herbert Jones.
E. Leete.
Sir B. Longbottom.
S. W. Melsom.
G. W. Partridge.
R. W. Paul.
Col. T. F. Purves, O.B.E.
C. Rodgers, O.B.E., B.Sc.
P. Rosling.
E. H. Shaughnessy, O.B.E.
J. W. T. Walsh, M.A., M.Sc.
S. J. Watson.

And

the Chairman and immediate Past-Chairman of each Local Centre.

Regulations for the Electrical Equipment of Buildings.

The Council have approved a number of alterations to the Eighth Edition of the above. Copies can be obtained from the Secretary for insertion in existing copies of the Regulations.

Associate Membership Examination.

The next Examination will be held on the 29th, 30th and 31st October, 1925. Candidates must be either Students or Graduates of the Institution or have lodged with the Secretary a duly completed form "E" for election as Associate Member. Entry forms for the Examination, which must be completed and returned by the 1st September, and particulars regarding election to membership of the Institution may be had on application to the Secretary.

Coopers Hill War Memorial Prize.

The triennial award of the above Prize falls this year to the Council of the Institution of Electrical Engineers, who have selected for the subject of competitive monographs "The Applications of Electricity to Metalliferous Mining." Intending competitors are reminded that the latest date for submitting their MSS. is the 31st October, 1925. The award for 1925 is limited to Corporate Members of the Institution who were under 30 years of age on the 1st January, 1925. Full particulars can be obtained on application to the Secretary of the Institution.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 June–25 July, 1925:—

* Annual Subscriptions.

ELECTRICITY SUPPLY TARIFFS: THEIR SIMPLIFICATION BY DISCRIMINATION.

By G. WILKINSON, Member, and R. McCOURT.

(*Paper first received 2nd February, and in final form 2nd March, 1925; read before* THE INSTITUTION *2nd April, 1925.*)

SUMMARY.

In the fourth annual report of the Electricity Commissioners, reference is made to the rateable-value system of charging for supply, the limitations of that form of tariff, and its unsuitability for general application. In this paper the authors suggest a two-part tariff, the first charge being based upon an agreed maximum demand in watts for which a definite number of units at 8d. per unit are charged per kilowatt of demand, and all over that number are charged at a low price per unit. Being based on the electrical demand of the consumers, this tariff can be offered to all classes of consumers; thus equity is secured in every instance.

Provision is made whereby the consumer may exceed his maximum demand; but should he do so the consumption is recorded on a second dial, the units thus registered being charged for at a higher rate. A simple, reliable, effective mechanism for automatically changing the record from one dial to the other is described.

Attention is directed to the important part which diversity and load factor play in framing tariffs.

It is now generally acknowledged that a full and free use of electricity is of vital importance to the industrial and social life of the community, and prominent leaders of all political parties have expressed their conviction that an abundant and cheap supply of electricity would greatly assist in the alleviation of the many social ills from which the State is at present suffering.

To achieve this object of a more extended, if not universal, use of electricity by all classes is the life work of all electrical engineers, and whilst improvements in the efficiency of the generating, distributing and current-consuming apparatus are of the utmost interest to them, there is no doubt that to the layman or the man in the street the most important point is the price per unit asked for his electricity service.

The consumer is to-day offered a bewildering choice of tariffs from which to select, and he has frequently expressed himself in very emphatic terms about their complexity and the difficulty experienced in making a choice. If electricity could be sold on the same terms as flour, tea, sugar, etc., viz. at a flat rate per unit with varying discounts according to quantity used, the average consumer would be better satisfied and much more amenable to suggestions that he should increase his use of electricity by purchasing other current-consuming apparatus in addition to electric lamps. Unfortunately we cannot get our tariffs framed on quite such simple lines, but the authors maintain that the sale of electricity can be made much less complicated than it is at present, while providing equity not only between the supply undertaking and its consumers, but also between the various classes of consumers themselves, both desirable characteristics which are lacking in many of the tariffs at present in vogue. Until the price charged to each consumer bears a definite and reasonable ratio to the profit made on his supply, the question of tariffs cannot be regarded as being satisfactorily solved.

There have been many papers and discussions on tariffs since the historic occasion when the late Dr. John Hopkinson first laid down the principle that each consumer should bear his proportion of the cost of the standing charges involved in providing his demand, and from the many systems evolved there has gradually crystallized the general consensus of opinion that a two-part tariff is the most equitable method of charging for electricity consumed.

Probably the most popular two-part tariff is the well-known "rateable value" system, which consists of a fixed charge, based on the rateable value of the premises, plus a low price per unit for all electricity used. The obvious objection to this tariff is, of course, that it bears no relation whatever to the electrical demand made by the consumer on the supply undertaking. Two consumers may, and frequently do, have premises which are equally assessed for rating purposes, and their respective electrical demands on the supply undertaking may be, and often are, very unequal, but they both have to pay the same fixed charge. Another objection to the "rateable value" system is that it is not applicable to every class of consumer but has been devised for and adopted by the domestic consumer only, because, generally speaking, he alone derives benefit from it as compared with other tariffs. The shopkeeper, the manufacturer, the hotel-keeper and all highly rated consumers are penalized, whilst the occupiers of all low-rated premises are subsidized if charged for electricity on the rateable-value system.

Another two-part method which is coming into vogue in some localities is to substitute floor area for rateable value as a basis for the fixed charge. This method, however, presents the same disadvantages and inequalities as the rateable-value system.

The authors submit, therefore, that while a two-part tariff is the best for stimulating the increased use of electricity, the fixed charge should be based on the electrical requirements of the consumer in watts or kilowatts, and on this alone. The consumer's electrical requirements will be classified on the basis outlined later in this paper at a definite amount for which he pays in the form of a minimum number of units at 8d. per unit and the residue at a low price per unit. Thus the average price will decrease as the hours of use increase during the 24 hours of the day; and only if, and when, he exceeds that agreed demand would a higher

rate be charged. Such a tariff can be offered to all classes of consumers without distinction, since it is based on their electrical requirements—the only sound and equitable basis for negotiation between supplier and consumer. This principle is at the root of the Wright maximum-demand system, but the authors' experience, in common with that of all central station engineers, has been that consumers do not understand its mode of operation, and when a consumer of any commodity does not understand the system on which he is charged he often has a suspicion that advantage is being taken of his ignorance. Under the proposed system the consumer can ascertain his position and liability unaided at any time, by observing his meter readings.

For such a tariff a cheap and reliable mechanism is required which, while limiting the consumer to his declared maximum supply at a cheap rate, will also automatically secure a higher rate of tariff during the time when he exceeds, either by accident or design, his declared maximum demand. Thus an equitable tariff is at once available—a tariff equitable not only as between the supply undertaking and individual consumers but also as between consumer and consumer, and this regardless of the particular times at which the supply is taken or the purposes to which is is applied.

The authors claim that they have devised a system and designed a simple and reliable instrument by which these substantial advantages can be obtained and the accruing growth of business secured. Briefly the *modus operandi* is as follows: The consumer, instead of having to wait until the end of the quarter or half-year to learn the amount of his more or less variable demand, with the assistance of the supply undertaking assesses himself to take a fixed number of watts as a normal maximum of his requirements, and for this demand he pays a fixed quarterly charge per kilowatt demanded at 8d. per unit, according to his classification. A two-rate meter is installed, on one dial of which all the current used under normal conditions, including the pro rata number of units at 8d., are recorded; after this deduction the residue is charged at the low price per unit. Should he at any time exceed the amount of this pre-arranged demand the mechanism called the "discriminator" comes into operation and automatically transfers the record of current consumed to the second dial, the units registered on that dial being charged for at a higher rate. It follows, therefore, that a consumer will use every means not to exceed his agreed demand, while at the same time he will endeavour to keep his demand as high as possible within the low-rate supply limit, thus giving the supply authority a much better load curve.

To assist the consumer and give him visible indication when he is exceeding his declared maximum demand a neon lamp or lamps may, if desired, be arranged at prominent positions and illuminated through the action of the "discriminator" changing the record of current consumed from the low-rate dial to the high-rate dial.

The mechanism to carry out the objects named by the authors must be of the simplest character, low in first cost, and entirely dependable in service for long periods without requiring attention at any time.

An Equitable and Simple Electricity Tariff for all Purposes.

The authors propose for this tariff an electricity meter of any dependable make fitted with two dials, one of which records the normal consumption and the other all units consumed under abnormal conditions.

The ordinary method of using such a two-rate meter is to have a time clock in connection with it which, by means of a shunt coil and a magnetic device, transfers the record to the second dial during light-load hours, all such consumption being charged at a reduced rate per unit, and restores the record to the original dial at an arranged hour, varying according to the time of the year. Obviously such a method can give only a very rough approximation to the actual cost and corresponding sale value of the units so supplied. In some cases the selling price compared with the cost of production will be excessive, whilst in others the price obtained may be actually below cost. One grave objection to this method of use lies in the employment of expensive and delicate clockwork mechanism. The authors have had wide and long experience with clockwork mechanisms and are convinced that an extensive use of expensive clockwork in connection with supply meters is a retrograde step, since the clockwork requires not only frequent winding but also considerable attention and repairs due to the unsuitable conditions under which it has to work.

The authors use the two recording dials in an entirely different manner; one dial, which is always in use under normal conditions, is called the "low rate" dial, and the other, which comes into use only when the consumer by design or accident exceeds his contract with the supply undertaking by imposing a heavier maximum load than he is entitled to under the terms of his agreement, is for convenience termed the "high rate" dial. When the load is reduced within the limits of the consumer's contract the record is automatically restored to the "low rate" dial.

These changes are effected in an entirely reliable and simple way by the mechanism called the "discriminator." This consists of a small coil or solenoid of few turns in series with the main circuit of the meter; within the solenoid is a light iron core or its equivalent shackled to the rocking bar operating either one or other of the dials referred to, according to its position. Normally, by reason of its own weight or otherwise, the rocking bar maintains the recording gear in circuit with the "low rate" dial, but, should the load at any time exceed the amount contracted for, the increased current in the series coil is strong enough to rock the bar, thereby disconnecting the "low rate" dial train and bringing into use the train operating the "high rate" dial, upon which the consumption is then recorded until the load is reduced to within the limits of the contract, when its record is automatically restored to the "low rate" dial. The units recorded on the "high rate" dial are charged for at a price sufficiently high to deter the consumer from exceeding the terms of his contract.

For instance, if after an initial fixed charge of 8d. per unit per kW demanded, for the first 45 units per quarter, the normal charge is fixed at ½d. per unit,

bringing the average price for all purposes to 0·809d. per unit on a 12-hour load factor, or 0·666d. per unit on a 24-hour load factor, a charge of 6d. per unit for all units recorded on the "high rate" dial would be ample to secure a fairly rigid adherence to the terms of the supply contract.

In a uniform tariff meter of this character it is of the utmost importance to obtain simplicity and cheapness, together with entire reliability of operation.

Figs. 1 and 2 show how these features are secured. Again, it is essential that the change-over from the "low rate" to the "high rate" dial shall be prompt and accurate without danger of the operating gear taking a neutral position clear of both recording mechanisms.

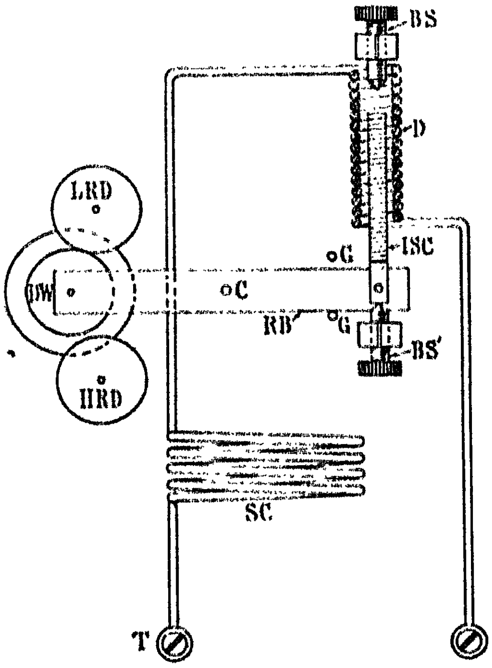

FIG. 1.—Diagram of connections of uniform tariff meter, a.c. type.

SC = meter series coil
D = discriminator
ISC = iron spiral coil with solid end
BS, BS′ = adjustable magnetic screws
RB = rocking-bar carrying driving wheel DW
LRD = low-rate dial train wheel
HRD = high-rate dial train wheel
C = rocking-bar turning centre
T, T′ = meter terminals
G, G = rocking-bar stops

This is achieved by the adjustable magnetic brakes at the top and bottom, in the form of steel screws as shown. These screws are set to positions which in the one case restrain the iron core from being lifted by the solenoid until the maximum load contracted for is exceeded, when the current in the solenoid is able to overcome the magnetic brake; thus there is the ample stored energy in the movable element to carry the gear promptly and definitely into train with the "high rate" dial. The restoration of the record from the "high rate" dial to the "low rate" dial when the load is reduced, is equally prompt and reliable, but the load to effect this must be reduced to a little less than the maximum load allowable under the contract.

The uniform-tariff meter as described is simpler and contains fewer parts than the ordinary two-rate meter, and no time clock whatever is necessary in connection therewith; also it is much less expensive and complicated than a maximum-demand tariff, which calls for two separate instruments and does not allow of the equitable grading of charges obtainable with the uniform-tariff meter.

The authors are of opinion that the fixed-charge part of the tariff should be built up on the basis of a quarterly charge at, say, 8d. per unit for a definite number of units per kW of demand, according to classification, and all over this number registered on the "low rate" dial to be charged for at, say, 1d., ¾d. or ½d. per unit according to the size of the undertaking and the local conditions under which the supply is furnished, all the units registered on the "high rate" dial to be charged for at, say, 6d. per unit. The charts in Fig. 3 show

I = bottom magnetic screw
J = back plate of counter gear frame

that the consumer is encouraged to make long-hour use of his agreed demand without exceeding it.

CLASSIFICATION.

The authors claim that the time has come when, in framing tariffs, supply undertakings must take more accurate account than they have hitherto done of diversity factor, not alone of consumers but of the different classes of use which the consumers make of their supply. The importance of taking diversity factor into account is realized when one remembers that the recorded maximum demand on the generators over a given period of time is always less than the aggregate demand of the consumers during the same time, while the figures

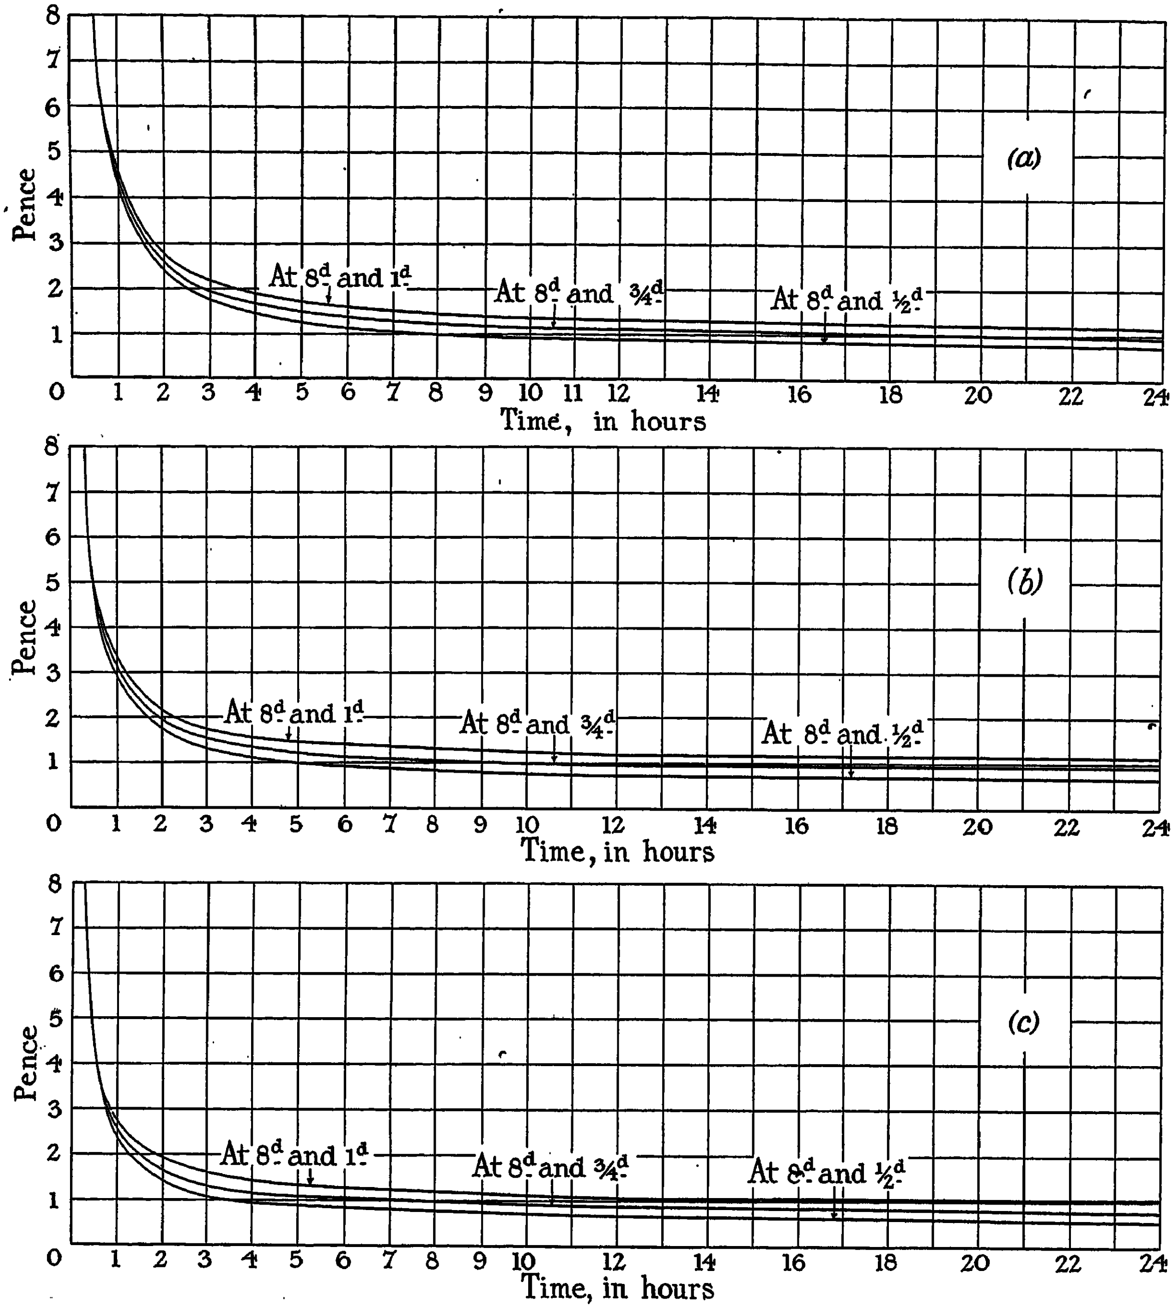

FIG. 3.—Average price obtained per kilowatt-hour at 8d. per unit.

indicating diversity factor in relation to the various uses made of the supply during each day have a wide range. Furthermore, the minimum number of units so charged will naturally vary with the character and size of works, the nature and class of the business, and the cost of coal, labour and other conditions and commodities involved in the business.

Under ordinary conditions equity calls for the division of the consumers into at least three classes, viz. factory and workshop, business, and domestic, and under these heads the examination of their various uses of the supply from the standpoint of diversity factor is interesting. Probably in numbers of cases they will work out approximately as in the accompanying table.

each consumer to increase the number of hours per day during which he uses electricity, the secondary rate per unit must be low. Briefly stated, a tariff such as that advocated by the authors will give the strongest possible incentive to the consumers to increase their hours of use and decrease their maximum demand on the supply station.

It will be clearly recognized that a simple and rapidly falling tariff as described constitutes the best possible stimulus for the introduction of additional electrical devices. Both the business man and the householder immediately begin to devise methods of long-hour use, and find it in many cases advantageous to introduce power absorbers of the nature of hot-water storage

Class	Lighting	Power	Heat	Proportion of total output	Diversity factor
				per cent	
(A) Factory and workshop	1	2	Nil	20	1 } Say for a town of less than 50 000 population
(B) Business	1	2	3	30	2
(C) Domestic	2	3	9	50	4·6
Average	$1\frac{1}{3}$	$2\frac{1}{3}$	4	100	—

Final average of (A), (B) and (C) = 2·5.

In the case of lighting in factories and workshops the diversity factor may seldom be more than unity, but in the case of domestic supply it is almost certain to be frequently more than 2. Similarly in the case of power in a factory the diversity factor may be less than 2, but in business premises it is likely to be more than 2. In the case of a present-day factory or workshop the amount of electric heating, which includes cooking, is so small that it may be neglected, whilst among the domestic consumers it is now fairly well established, and confirmed in Mr. S. C. Hurry's recent paper before the British Electrical Development Association, which summarizes the replies from 20 public supply engineers, that the cooking load has a diversity factor of 9 to 10. Thus the figure of 9 which we have taken is justified. By arranging the various uses of the different consumers we arrive at an average diversity factor of 2·5.

Diversity factor is, however, not the only consideration in framing a tariff, as the load factor is very important from the supplier's point of view. To obtain a high load factor is the object which attracts us all, and an attractive tariff will help to improve the load factor both of the individual consumer and of the undertaking from which he obtains his supply. If, therefore, a tariff is arranged in which the standing charges are secured based on the demand required, and which also encourages

not only for culinary and lavatory use but also for room-heating purposes. The authors suggest also that in numbers of instances a sound case can be made out for the introduction and use of storage batteries deriving their charging current from the supply undertaking during the hours of light load and discharging their current on heavy load, thus keeping down the maximum demand and thereby reducing the number of units chargeable at 8d. In some cases by these and kindred devices it will be possible to approximate to a 24-hour or 100 per cent load factor and thus obtain the supply at an average rate not greatly in excess of the actual cost of production to the supply undertaking.

This means that a considerable proportion of the capital-outlay burden will be transferred from the supply undertaking to the consumer; to the consumer it will mean vastly improved social amenities in the shape of automatic hot-water supply, thermostatically controlled room-heating, ample light at cheap rates, electric cooking, washing and other labour-saving devices, while to the manufacturer it will mean a greatly increased demand for his commodities with growing prosperity and happiness all round. Incidentally, but by no means an insignificant item, in big towns and cities it will secure a clearer and largely fog-free atmosphere.

[The discussion on this paper will be found on page 856.]

ELECTRICITY SUPPLY TARIFFS.

By H. M. Sayers, Member.

(*Paper received 9th March, and read before* The Institution *2nd April,* 1925.)

Summary.

The paper deals with tariffs for domestic supply.

A rational and practicable basis of charging is:—Cost, plus a reasonable return on the capital employed.

Distribution costs are very heavy; their reduction requires more attention than it has received.

"Copper cost" of distribution is largely (and generating cost somewhat) dependent upon the form factor (shape of load diagram), as well as upon the load factor of each section of a distribution system. This and other distribution costs do not follow the same laws as the costs of generation in respect to load factor and form factor. The cost of "units unaccounted for" increases at each step; it is necessary to measure them, and to take the necessary steps to reduce them to a minimum. A good load factor in one section does not compensate for a poor load factor in another.

The consumers on any distribution network could be commercially charged a uniform flat rate determined by their aggregate load factor (i.e. taking into account the diversity factor among themselves), but this would penalize some to the advantage of others.

The suggestion is that domestic tariffs should consist of a number of flat rates, based on a classification of consumers according to their loads and their class diversity factor and load factor. This will encourage domestic loads of a desirable nature.

A limitation of lighting loads in proportion to other loads may be necessary at present, but domestic lighting will probably cease to be a predominant feature of the peak loads, as cooking, heating, and other domestic uses become more general.

This discussion of electricity supply tariffs assumes that a rational, practical tariff must be based upon costs.

The principle of charging on the basis of the value of the service (what the traffic will bear) can be followed only to a very limited extent in the case of a public utility service carried on in the presence of competitive agencies and under statutory regulations which forbid "preference" and fix maximum prices.

A second assumption is that it is an obligation of a statutory undertaker to meet the demands of the public to the fullest extent practicable—subject to obtaining a reasonable remuneration for the capital, skill, and labour employed in giving the supply. This obligation is rather explicit in the law relating to electricity supply.

The practice of basing tariffs upon costs is widely adopted for supplies to factories, etc., and for traction and bulk supplies to authorized distributors. It is shown by the prevalence of coal clauses, two-part tariffs, power-factor charges, and, in many contracts, by provisions for the periodical revision of prices, subject to arbitration, where the arbitrator can do no other than satisfy himself what is the cost of the supply, including capital charges and a reasonable profit.

In these large-consumer classes an upper limit of price is given by the cost to the consumer of generating his own supply, including in the cost the consumer's estimate of the cost of the capital invested, space occupied, additional cost and trouble of management; while the prohibition of preference means that large consumers generally get the reflected benefit of those who are best placed to produce for themselves. For such industrial consumers the load conditions can be ascertained pretty closely, and the consequent cost of the supply can be estimated with fair accuracy. The practice has met with brilliant success.

For domestic consumers in general the case is very different. The individual capital costs of services and meters, and of working costs such as meter reading and maintenance, accounting and collecting, are relatively high—highest for the smallest consumers. The load characteristics of domestic consumers vary widely. They are all lighting consumers—the majority nothing else—but electric ironing, cooking, heating, washing, and small-machine driving are being slowly adopted, and the load characteristics vary with the extent to which these other uses prevail. Which tariff (or tariffs) to adopt for such domestic supplies is the important question to-day.

Accepting the principle that a rational, remunerative tariff—or tariff scale—must be based on costs, it is proposed to examine the elements of the cost of supply and how these vary with load characteristics; and to submit that a tariff based on a classification of domestic consumers by their class load-characteristics will attract consumers, improve the general load character of the undertaking, increase the return on the invested capital and meet general public interests.

At present, domestic supplies are mainly for lighting. Where the load is of this character the load factor is of the order of from 10 to 12 per cent; or the yearly output is the equivalent of the maximum demand used for from 900 to 1 100 hours per annum. Under these conditions the capital charges of a municipal undertaking—which includes the minimum guaranteed return that will attract capital—are generally greater than the working costs. In such a case, to raise the load factor of the system from 10 to 30 per cent will reduce the costs per units sold by at least one-third all round, and probably more.

The influence of load factor upon generating costs has been studied in great detail, and it is well known that for any given station the curve of costs plotted against output in a given period resembles the Willans steam-consumption line for a particular engine, or the

Parsons coal-consumption line for a particular battery of boilers. It is a straight line which cuts the cost axis at some amount per period for zero output. If this is tested for any station it will be found that the intercept on the cost axis for zero load is not constant; it varies with the maximum load reached during the period. For example, the zero output cost in June will be lower than in December for any British station with a predominant lighting load; lower in gross amount, but higher per kilowatt of maximum demand and per unit sent out. For a station with a predominant industrial demand, but still getting its peak in mid-winter from superposed lighting and factory loads, the June zero-output cost-intercept is also lower than the December figure, but the costs per kilowatt of maximum demand and per unit sent out are lower.

The capital charges per period do not vary with either the maximum load or the output. They are a constant addition to the zero-output working-cost.

Some other points about generating costs which it is necessary to make here are: First, that while generating-station costs are not directly affected by diversity factor, but by the load factor which is the resultant of all the loads and the diversity factor among them, yet the diversity factor does affect the correct allocation of station capital charges to different loads. A very simple (and quite unpractical) example is, that if each of four consumers gives a station load of 1 000 kW for 6 hours per day without overlap, each of the four should pay one-fourth of the capital charges (including profits) proper to a load of 1 000 kW; whilst if one consumer gives a station load of 1 000 kW for 24 hours every day, he should pay the whole of the capital charges on 1 000 kW. A uniform kW charge in a two-part tariff would not be equitable as between the two cases. As a more practical example, an ice-making plant which runs only during the summer months may be equitably debited with, say, half the annual kW charge relating to the station, the other half being met from, say, the heating load utilizing the same generating capacity in mid-winter.

The effect of load characteristics upon distributing costs has not been scrutinized so closely as the effect upon generating costs. It is more complex, and the elements necessary for evaluation are not so readily ascertained. The subject requires greater consideration. The fact that distribution costs and charges are often from two to four times the costs of generation per unit sold shows that there is ample room for investigation and improvement.

The relations between distribution costs and load characteristics are not of the same form as those between generation costs and load characteristics, and they are different for different parts of the distributing layout. For example, let us take the ohmic losses in the mains. Any main has the maximum physical efficiency of 100 per cent at the useless load of zero, when its commercial efficiency is negative; whereas the physical efficiency of generating plant is zero at zero output, and a maximum at some load not far from that of maximum commercial efficiency—the largest output rate which can be carried without damage to any part.

The maximum commercial efficiency of a main is given by the Kelvin relation. Ohmic losses vary with the square of the instantaneous load. Consequently, the distribution of the loads in time has a large influence upon their proportion to the energy delivered, and upon the loading for minimum cost per unit delivered. If a given number of units is delivered through a given main in a given period—say one day—to a steady load lasting 6 hours per day, the rate of ohmic losses is 16 times as great as for a steady 24-hour load giving the same delivery; or, in other words, the units lost in transmission will be four times as great in the 6-hour case as in the 24-hour case.

Increased transmission cost due to the lower load factor cannot be entirely avoided by increasing the copper section of the main. For suppose that the copper section complies with the Kelvin relation for the 24-hour steady load (i.e. copper capital charges equal the cost of the losses), then to maintain that equality the copper section must be doubled for the 6-hour load, when the ohmic losses will also be double those for the 24-hour load. So the maximum transmission economy for the 6-hour load will give double the cost per unit delivered of the 24-hour load, for both copper capital charges and ohmic losses.

Applying this to the hypothetical comparison of one consumer giving the station a 1 000 kW load for 24 hours, with four consumers each giving that load for 6 hours per day without overlap, it appears at once that the distribution costs in the two cases can only be identical if all four consumers are supplied through the same length and size of main as the one consumer, and that the four services are taken from the same point. Suppose that they are not so located but that a main has to be laid to each, of the same length as to the one consumer. Then each main will have a 25 per cent load factor. It will, if designed for maximum economy, have half the copper section and twice the ohmic losses and voltage-drop of the economic main for the single 24-hour consumer; so that the total copper employed, the capital charges upon it, and the annual losses in the four mains, will each be twice as great as for the main supplying the 24-hour consumer. Hence the kW charge *qua* distribution for the 25 per cent load factor 6-hour consumers should be twice that for the 100 per cent load factor 24-hour consumer.

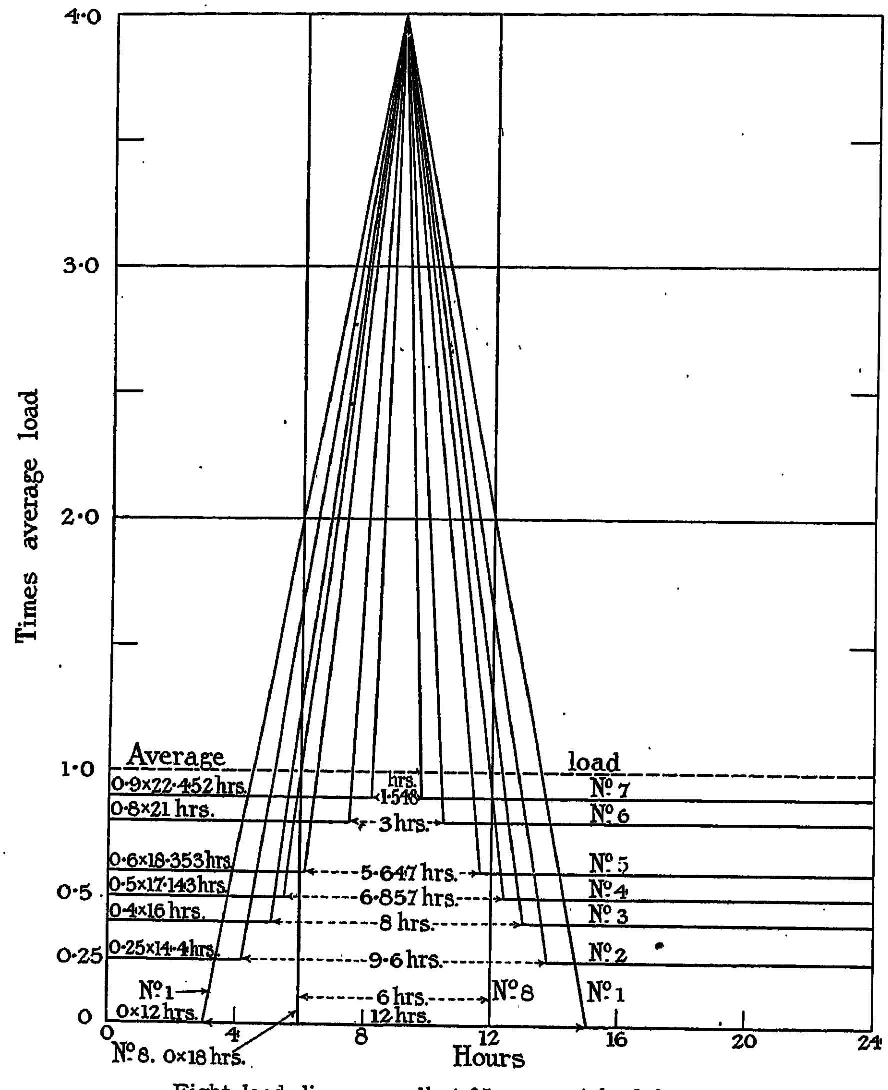
It will be seen that if the condition postulated of equal load at the station busbars is observed, the units sold to the four consumers will be fewer than the units sold to the one, by the difference in mains losses; or, if the units sold are the same, the station load and the units generated will be greater for the four 6-hour consumers than for the one 24-hour consumer. The station costs per unit sold will be greater for the four than for the one, and the extra cost is a distribution cost, though shown in the station expenditure.

The extra station cost could be avoided by making each of the four mains the same size as the one 24-hour main. Evidently the capital charges on the copper would then be four times as great per unit sold, instead of twice as great, and the mains losses would be kept at the same amount; in other words, instead of equality of the copper capital charges and the cost of copper losses, the capital charges will be four times the cost

of the losses, and the total of the two will be in the ratio of 5 to 2, compared with the total for the single 24-hour consumer, instead of in the ratio of 4 to 2 with the correct economical section.

This example illustrates the fact that diversity factor among loads has its full effect on the load factor of the station supplying them, but it only improves the load factor on the distribution side if the diverse loads are supplied through the same mains. The cost of distribution through any one feeder or section of a distribution system with a 10 per cent load factor is not in the least reduced by the existence of other sections enjoying a 50 per cent load factor. But if a number of sections are supplied through one feeder, the load factor of the feeder will be the better for any diversity factor existing between the sections.

Diversity factor between loads means a difference in the time incidence of the individual maximum demands. Numerically it is the ratio between the sum of the individual maximum loads (whatever the time at which they may occur) and the maximum of the combined loads. If the individual maxima are simultaneous the ratio is unity. If they are not simultaneous the combined maximum will be less than the sum of the individuals, and the quotient of the larger divided by the smaller quantity will be greater than unity. The combined load factor is equal to the separate load factor multiplied by this ratio—the diversity factor—where separate load factor means the ratio of the units delivered during a specified time to the product of the sum of the individual loads and the time.



Eight load diagrams, all at 25 per cent load factor.

The costs of transmission depend upon the form of the load diagram as well as upon the load factor. It may indeed be said that the form factor is the more important. For any load factor the worst condition for cost of transmission is that of a steady load for the load factor percentage of the load period, and zero load for the remainder of the period, i.e. a rectangular load diagram standing on the zero line. A 25 per cent load factor will be shown by a load diagram with a steady

load for 6 hours per day and no load for 18 hours per day, when the transmission costs per unit delivered will be twice as great as for a steady 24-hour delivery, or 100 per cent load factor. For any load factor whatever, the maximum multiplier or "form factor" is the square root of the reciprocal of the load factor. For any time distribution of load other than that represented by a rectangular load diagram—maximum load or no load—the form factor lies between that maximum and unity, but can only be unity for 100 per cent load factor. The average load over the whole periodic time multiplied by the form factor is the R.M.S. load, and is the value to be used for finding the most economical copper geometry of the triangle, the slopes on either side of the apex may be any pair fulfilling the condition that they cut the time base 12 hours apart and meet at four times the average load taken over 24 hours.)

Actual load diagrams are rarely of simple form and it is therefore generally necessary to measure, square, and take the mean square of a sufficient number of ordinates, in order to get the form factor; so that to calculate economical copper sections one must possess or forecast a load diagram.

Calling the ohmic losses the working costs of the main, both the copper capital charges and the working costs increase as the R.M.S. load, which is quite different

TABLE OF LOAD CHARACTERISTICS FOR DIFFERENT LOAD DIAGRAMS, ALL GIVING 25 PER CENT LOAD FACTOR.*

(See Load Diagrams in the Figure.)

No. of curve	Description of load	Mean square factor	R.M.S. or form factor multiplier for 100 per cent load factor copper costs	Load factor of losses	Voltage-drop at top load and per cent of plant to meet them. Delivery volts assumed constant	Generating capacity for top-load losses †	Daily loss †

* The table shows that as the copper section is diminished in relation to the maximum load, with falling form factor, so as to keep copper capital charges and losses costs equal, the voltage-drop and capacity to meet it at top load increase. The simple Kelvin relation upon which the table is worked assumes that all units lost have a uniform value. They clearly have not, as their cost must increase as the load factor of the losses decreases—or as the plant capacity needed to keep up the voltage increases. In any actual case this effect is diminished if there is a diversity factor among the feeders. The simplest form of correction to the simple Kelvin expression is to take a higher cost for the lost units. If boosting is needed, the lost units must be given the proper higher value including capital charges, etc., on the booster, or its equivalent.

† These columns give the comparative daily losses for a daily delivery of 12 000 units in every case, based upon those for 100 per cent load factor, i.e. for a steady load of 500 kW delivered, and the additional plant required at the peak load to keep the delivery voltage constant.

For the 100 per cent load factor the losses are taken as 5 per cent of the units delivered, or 600 units per day: the plant capacity 525 kW. For the 25 per cent load factor the peak load is 2 000 kW delivered, and the plant capacity at the peak 2 000 kW, plus the amount given under the heading "Generating capacity for top-load losses."

section, from the "Kelvin current density" calculated for 100 per cent load factor.

To show how form factor varies with the load diagram for the same load factor, say 25 per cent, let the load diagram be triangular, rising from zero at a uniform slope to four times the average load, and falling again at a uniform slope to zero. The time base of the triangle will be half the duration of the period, say 12 hours per 24 hours. The mean square value will then be $2\cdot\dot{6}\dot{6}$ times the average over the 24 hours, and the form factor $\sqrt{(2\cdot\dot{6}\dot{6})} = 1\cdot63$, instead of the values 4 and 2 for the rectangular load diagram. (From the from the relation between the capital and running charges of the generating plant for various load factors.

For any but the rectangular load diagram the load factor at the delivery end of a feeder is higher than the load factor at the station end, because the load factor of the losses is lower than that of the useful load. Also the maximum losses are an addition to the peak load and add to the station capital chargeable against the units sold through the feeder. The total or combined peak load of distribution losses takes up part of the station capacity and diminishes the paying load which can be supplied from the station. This loss of plant

capacity is allocated to particular feeders in proportion to their individual peak loads, and inversely as the diversity factor among them, or the maximum load of each divided by the diversity factor.

The diagrams and table on pages 852 and 853 illustrate these points. The load factor is 25 per cent in all cases, but results from different load diagrams, these being of simpler form than are usual in practice, for ease of calculation. The last two columns of the table are of actual kW and unit values for the following assumed conditions: That the load diagram is for 24 hours; that the feeders are of equal length and each delivers 12 000 units in the time; and that the "Kelvin current density" for 100 per cent load factor (a steady 24-hour load of 500 kW delivered) gives a drop of 5 per cent of the delivery pressure, representing copper losses of 600 units per day. The other columns give relative figures.

One could go on to show how the capital charges and running costs of transformers, converters, switchgear substations and the like vary with the load factor and the shape of the load diagram. It must suffice to say that in every case there is a large proportion of the total annual charges which is fixed by the maximum demand upon each item, and is consequently shown in the cost per unit as inversely proportional to the load factor; also that this proportion is individual to each section of a distributing layout, so that there is no compensation for a badly-loaded section by the existence of better-loaded sections. It is only the feeders, substations, etc., feeding a number of distributing sections that get the benefit of diversity factor. Generally the copper sections of the ultimate distributors to which consumers' services are connected have to be determined by voltage variation rather than by economy; hence the capital charges will depend upon the maximum loads (strictly, the integrated product of loads and distances at the peak loads) and the distances between the feeding points and the most remote services. The losses will still be those corresponding to the R.M.S. loads.

Enough has been said to show that the relations between costs per unit sold, load factor and form factor, are not alike for generation and distribution; the latter are more complex, and more affected by the load characteristics.

Distribution losses ("units unaccounted for") are paid for in the generation costs. Generation costs "per unit sold" include these distribution costs, a fact not always recognized, which makes the comparison of station costs upon the "units sold" basis quite misleading where the distributing conditions are not equal.

Cost per unit sent out is the only fair basis for determining station economy; the commercial efficiency of a station has no definite meaning where sales are effected through a distributing system which puts its lost units to the debit of the station.

The value of the distribution losses per unit increases at each link in the chain between the station busbars and the consumers' terminals. The units delivered by a feeder cost more than those delivered to it, by the sum of the losses and the capital charges on the feeder. The units delivered by converting plant to direct-current distributors cost considerably more than the units taken from the alternating-current feeder, by the sum of the losses, capital charges, and attendance costs of the converting substation. The cost of the losses in the distributors is the cost of the units delivered to them, which is greater than the cost per unit sent out from the station. This greater cost should be used in calculating economical copper sections for each stage. Most costly of all are the units lost by defective meter registration. Their value is their selling price, for they are consumed and not paid for.

For the reduction of distribution costs a much larger use of measurement is necessary. It is impossible to control distribution losses, with due regard to economy of capital, unless one knows their magnitude at each stage. Reduction seems necessary, when it is realized that there are systems where the units sold are about 55 to 60 per cent of the units sent out.

This disquisition on distribution costs is entirely pertinent to the question of tariffs for domestic supply, first, because the total of distribution costs, capital charges and losses is a serious element in the total cost of supply, and secondly because load characteristics affect these costs more, and not in the same way as they affect generation costs.

This can be shown by considering how the costs per unit sold are made up. Start from the consumer's terminals. To give a supply capital has been spent by the undertaker upon the service cables, meter, supply fuses, laying, jointing and fixing. This is individual to the consumer, and on that capital the consumer should pay a certain annual percentage. The outlay, on the average length of service, can be represented by some minimum cost, plus an amount roughly proportional to the declared or connected load. This item of the charge might be included in a connected-load charge, which should go by steps and would be appropriately included in a "meter rental" charge. If it is distributed over the charge per unit, evidently it should vary inversely as the individual consumers' load factors, which is equivalent to making it an element of a kW charge in a two-rate tariff of the usual kind. But the kW figure for this item of charge should be the number of kilowatts of declared or connected load, not the estimated or observed maximum demand.

The next step is the distributing main to which the service is connected. It will generally serve a number of consumers. How is the annual cost of it to be allocated between them?

Any distributor with any load distribution along it can be reduced to an equivalent main of the mean length, supplying a load at its end which is the equivalent in magnitude, units delivered in a given period, and load diagram, to the aggregate loads of all the consumers served. The maximum load is the sum of the individual consumers' maxima divided by the diversity factor among them; and the load factor of the distributor is the ratio of the total units delivered, to the product of that combined maximum and the hours covered by the period.

The capital cost taken must evidently be that of the actual distributor; for though the equivalent main should have the same copper cost, it will generally be

shorter, and the cost of laying depends upon the length and other circumstances. The copper cost and the losses will be determined by the permissible voltage variation between the feeding point and the most distant services.

The same process should be followed back through feeders to distributors, substations, feeders to substations, etc., which will give as a result the total cost per unit delivered at any particular feeding point, including the capital charges and the cost of the losses. At each converging point of different loads, the benefit of the diversity factor between the constituents is taken into account, and the costs of labour, etc., added.

Evidently the cost of the units sold through the particular ultimate distributor in the course of a year is made up of:

(*a*) The cost of the greater number of units delivered to the distributor, including all the capital charges and the cost of the losses up to the feeding point.

(*b*) The capital charges on the distributor.

(*c*) The capital charges on the services, meters, etc., and the cost of meter-reading, etc., for all the consumers.

It has already been suggested that (*c*) should be charged to the individual consumers as a meter rental, or it may be as a charge per kilowatt of connected load.

The total of (*a*) and (*b*) divided by the total units sold gives a sum per unit, which with a reasonable addition for profit—unless profit is included in the capital charges at each step, which is the sounder way—is a proper average price for all the consumers.

This is a "flat rate," which, however, includes a kW charge based upon the aggregate load factor, an average charge per kilowatt of the individual consumers' maximum demand divided by the diversity factor among them. It is really treating the whole of the consumers on that distributor as a single consumer, and charging that consumer a maximum demand rate, plus a unit rate. This would be quite equitable if all the consumers had similar load characteristics; but if some have large peaks at the time of aggregate peak load, and low load factors, and some have more favourable loads, the good would be paying for the less good and would have some reason to complain. Also, the price would be higher than necessary for the good, and too low for the less good.

Such a calculation does, however, permit of the determination of flat rates for hypothetical groups of consumers with similar load characteristics, and an assumed load density (kilowatts per unit length) along a distributor. The resulting flat rates will be minima for each class of consumer investigated, which must be loaded to meet the fact that consumers will not usually be in groups of homogeneous load characteristics.

The practical application of the method which the author suggests for arriving at tariffs for domestic supply is, first, to classify consumers by their load and diversity factors. The best basis for this is observation of selected groups with similar proportions of connected load for different uses. Something of this kind has already been published, for example in Mr. Gillott's paper on "Domestic Load Building," * and very likely more has been done but not published.

* *Journal I.E.E.*, 1923, vol. 61, p. 197.

Mr. Gillott's paper showed that in a homogeneous group of consumers using cooking apparatus the diversity factor was about 9, so that the kW charge to them would be properly one-ninth of the individual maxima. He also showed that this charge would be fairly well represented by charging the lighting rate for their lighting consumption, and a much lower rate for the rest.

There are many tariffs in use based upon the same idea—"telephone," rateable value, floor area, quarterly charges per lamp of unit wattage installed, and others—all endeavouring to fix a basis which represents a kW charge. Very generally the underlying notion is that lighting is the measure of the peak load to be charged for on the kW rate for domestic supplies. This notion may be generally correct at present, but the author suggests that the domestic lighting load will become of diminishing importance as "other uses" become generalized. Many of the two-part domestic tariffs referred to above are difficult to justify on any logical ground; and smaller householders are repelled by an obligation to make relatively large fixed periodic payments. Tariffs which permit the use of prepayment meters are indispensable to the generalization of domestic electrification.

As there will be for a long time to come—perhaps always—considerable differences between the load characteristics of domestic consumers living in the same districts, it will not be correct to use the minimum rates worked out on the hypothesis of homogeneous groups on each distributor. The actual rates will have to be higher than these minima, because each class, scattered over the supply area and mixed up, will not be the equivalent of a single consumer.

The practical method of classification can be worked out only for each supply area, because local habits and customs, prevailing industries, etc., will have their effects on the load characteristics. The general method, the author suggests, should be to ascertain the load characteristics of consumers with various proportions of lighting, cooking, heating, motor, etc., appliances, and from these observations define the classes and fix the rates.

Some things must be averaged. It is not practicable or legal to make differential charges depending upon the distance of consumers from the generating or bulk-supply source, so that an average distance and cost must be taken. There is the legal prohibition of "preference" to be observed; hence different flat rates must be based upon defensible differences in circumstances.

For the immediate future it may be advisable to limit the maximum lighting demands of domestic consumers under these tariffs. There are various forms of limiter available. Generally, in small houses the lighting circuit is bound to be separate from the cooking, heating, etc., circuits, so that the use of current limiters is feasible. One rather attractive proposition is to connect the lighting to the circuit supplying a heat-storage tank, with a limiting switch to turn off the heater as soon as more than one or two lamps are in use. This would make the lighting part of a load with 100 per cent load factor. Current limiters and

the like cannot be discussed here, but a condenser in the lighting circuit on alternating-current distribution has attractions.

The object of this paper is to show :—

(1) That the present heavy ratio of distribution to generation costs can be materially improved by improving the distribution load factor, especially by improving it all over any supply area.

(2) That it is necessary to keep control of distribution economy by measurement, and to apply the known principles of economic design to distribution networks.

(3) That tariffs recognizing load factor and diversity factors of domestic consumers by classes are practicable and will attract the most desirable domestic load, thereby improving the utilization of distribution systems and permitting progressive reduction in supply charges.

Discussion before The Institution, 2 April, 1925.

Lieut.-Col. W. A. Vignoles : Surely all the electric supply undertakings in this country must by this time have realized the necessity for developing the domestic load, and have already provided some sort of tariff to encourage it. If that is so, why are we once more discussing this question of tariffs ? Having come to the conclusion that this discussion was not required, I examined some statistics which had been given me, to see whether my contention was justified. I find that out of 260 towns, 144 are using multi-part tariffs, and as regards other activities 117 are hiring out apparatus, and 109 have showrooms. The figure 144 is somewhere about 50 per cent of the total, and this seems to show that I am wrong and that there is still need to discuss this question of tariffs. What is actually required, however, is more internal propaganda to convince the supply undertakings that it is time they pushed the sale of electricity for purposes other than lighting and adopted one of the tariffs which can be explained to the consumer in an easy manner.

Mr. Sayers's system is essentially a series of flat rates, but surely this will be impossible to work. A consumer has electricity for lighting purposes, and he begins to use it for some other purpose. As he does so he will go from one class to another class, and will never be able to tell which class he is in, and the man who is trying to sell him electricity will not be able to tell him. Tariffs cannot be devised scientifically to provide a revenue exactly in agreement with the cost of supplying a particular consumer; it is only possible to get a rough approximation.

Messrs. Wilkinson and McCourt have gone back to the complicated system of Mr. Wright, of so many units at a high figure and so many units at a low figure. Because no one could ever make the consumer understand how many units he ought to have at the high figure and how many at the low figure, the system was given up. The present authors complicate it still more by giving the consumer so many units at 8d., so many at ½d., and then switching him back to a third rate of 6d. Further, this necessitates a special piece of apparatus which supply undertakings cannot afford if they are going to sell electricity on commercial lines. There are thousands of consumers in each town, and it would be impossible to substitute this special meter for all the existing ones. We must have a tariff by means of which a consumer can be charged according to the reading of a single meter. A more serious objection to the authors' system is that it is based on the consumer's maximum demand for all purposes. The consumer is therefore not getting the benefit of the diversity factor between one consumer and another.

The more I study these two papers the more I come to the conclusion that the only practical tariff is a straightforward two-part tariff. It must be such a tariff that the salesman can go to the consumer and say "Your first charge is so much per annum; in addition to that you will be required to pay so much a unit for the energy which is metered." The running charge should be the lowest possible figure—1d., ¾d. or ½d., if it is possible to get down to that—but it certainly should not be more than 1d. I am quite certain that this is the system which will eventually be used—a fixed first charge and a low running charge. This has been proved in many towns to be a good selling tariff. The consumer understands it, and thousands of consumers are already on it. The Electricity Commissioners are anxious about tariffs which can be made compulsory without giving the consumer the option of going on to a flat rate. Whilst a rateable value tariff is quite satisfactory in some towns—it is in mine—it cannot be said that 18 per cent on the rateable value in one town is the same as 18 per cent on the rateable value in another town. All that one can say is that 18 per cent on the rateable value in such and such a town produces an amount of money which covers the standing charges, and perhaps 20 per cent would be required in another town to cover them. I quite admit that it is difficult for a Government Department to have to make such a tariff compulsory, but this difficulty will no doubt be overcome by the Committee which I understand is being formed. I think they will find some method of fixing this first charge; I should like to say, however, that whilst the Grimsby undertaking was the first to get powers to enforce such a tariff, we have not enforced it. We rely on a high flat rate to encourage people to come on to the rateable value system, and we shall only ask the Commissioners to approve a compulsory tariff in special cases, or in cases where we go out into the rural districts, where it means possibly a large capital expenditure for each consumer. I do not think, however, that we shall ask for any such special tariff for the town supply.

I maintain that this tariff problem is settled, and that the sooner we get on with the selling of electricity on a two-part tariff the better it will be for the industry. I believe that a good deal of this discussion on tariffs has arisen from the fact that many engineers in supply undertakings think that they can sell electricity by devising a tariff. I hold that that is entirely wrong; it is impossible to sell electricity by a tariff only. I am quite sure that all the engineers of the big, successful undertakings are of the opinion that the only way to sell electricity is to do so by means

of salesmen, the tariff being a part only of his equipment.

Captain J. M. Donaldson: Flat rates have proved in the past to be exceedingly unfair either to the consumer or to the supplier, and it is very difficult to see how they can be otherwise than unfair. Mr. Sayers's plan of selecting and grading his consumers raises another very practical difficulty—that some individual will have to make the selection, and this will be a thankless job. The maximum-demand system, which has been spoken of rather scathingly by Col. Vignoles, but which, after all, is the basis of all the tariffs we use, is useless for direct application to a domestic load. One cannot, with any commercial hope of success, apply any tariff depending on the demand which a heater or cooker may put on the mains at any time, as it is impossible to specify what that time will be. The demand is relatively so large in comparison with the lighting demand that no single tariff will fit both.

I found the results given in Messrs. Wilkinson and McCourt's paper rather difficult to understand, because it seems to me that unless the device is applied only to the lighting circuit, and unless the lighting circuit is kept absolutely distinct from the power circuit (which, of course, is a mistake, in some cases at any rate), a consumer is bound to get on to what I may call the "penal rate" every time a cooker or heater is used. The fixed charge of 8d. must be based naturally on the demand for lighting, and quite properly of course; but as soon as ever a heater or cooker is put on it is bound to switch the meter on to the "penal rate" and, so far as I can see, the consumer will find a difficulty in getting off it. Some figures which I took out showed that in an ordinary case the price per unit on the first scale would probably be about 3½d. for heating or cooking. On page 849 the authors suggest that the unfortunate consumer is going to be asked to install storage batteries on his premises to take the load at odd times and charge up. Whilst this would no doubt be welcomed by the supply undertaking, I think that the experience gained by people since the introduction of broadcasting has not rendered the storage battery very popular. It really comes to this, I think—that it is necessary to have a two-part tariff with a fixed rate, and a low rate at which current can be obtained for any purpose. It is quite true that it is not desirable that the heaters which are installed nowadays should be connected to the lighting circuit; it would hardly be practicable. At the same time there is a great deal of other apparatus, such as irons and toasters, and even bowl fires, which can very conveniently and cheaply be put on to the lighting circuit. Therefore any tariff which entails separate power and lighting circuits is really a backward step. As far as the fixed part of the tariff is concerned, it will really be based on the maximum demand for lighting, and if this can be arrived at in a convenient manner it is better to do so, because the rateable value is only arbitrary, and floor space equally so, people having different ideas of how they propose to light their homes. My preference is for a system in which the fixed charge is based on the lighting demand, or rather on a fixed proportion of the lighting wattage installed. My experience is that such a system works very well, except in those cases where a large number of decorative lights are used. Such cases can, however, always be dealt with by making a test which indicates exactly what the demand is normally at any one time, and basing the tariff on that figure. It appears to me to be quite useless to attempt to base a demand charge on the heating and cooking load, because no one knows how it will work in practice; and unless an undertaker can tell a consumer that it will only cost so much per hour to run, say, a heater, I am afraid that the consumer will look upon him with suspicion. If there is a flat rate, however, and a fixed charge depending only upon the lighting, then of course it is possible to say definitely what it will cost to run the heater for an hour.

Mr. J. R. Blaikie: Mr. Sayers states that the cost of mains is from two to four times the cost of generation, but I think that that figure calls for some substantiation. Col. Vignoles seems to think that electricity cannot be sold by means of tariffs, but in my opinion the whole history of electrical development has shown the immense value of tariffs. Dr. Hopkinson set out to reduce the cost of electricity below that of gas, and he did so entirely by what is known as the two-part tariff. If we had not had the advantage of Dr. Hopkinson's work we should be in an entirely different position to-day. One of the failings of the majority of papers written on the subject of tariffs is that they do not show how these various stand-by or first costs are arrived at. It is generally taken for granted that they consist of a certain cost and a certain running cost. It is very important to arrange these two factors suitably, and we have continually to split up the segregation of consumers to do so. If we take the original Hopkinson principle we have a number of assumptions. One is, for instance, that the consumers are all at an equal distance from the point of generation. That, of course, is a very great assumption, and the cost of supplying a consumer at a long distance is very much greater than the cost of supplying a consumer at a short distance. It might be possible to devise some system of tariffs which would take the distance into account and possibly average the kilowatt demand. Such a system might be worked out on the rate per yard by taking simply the length of a consumer's frontage. We cannot, however, take the distance of the consumer from the station; but every consumer is slightly further from the station by reason of the other consumers' frontages. If every house in a street were connected to the electric main, the sum of the frontages would represent the total length of the main. By dividing the total cost of the mains by the total frontages the price could be fixed. This method could also take into account the Hopkinson principle, from the point of view of mains, by apportioning the standing charges per yard of main to keep it up to pressure. It would be quite possible to work out a tariff which would be as successful as that based on the rateable value, or floor area simply on the frontage of the house or premises, and possibly, as Mr. Sayers points out, it might be based on the square of the frontage. The coal consumption in a Parsons line shows that somewhere about 10 per cent of the total coal is used as a standing charge. That is a very essential point. There are a

great many engineers in the country who believe that the stand-by charge in coal is simply that required for banking the boilers and that it is not the belt that occurs under the straight line that cuts the axis of the coal scale. It is a very important point, because it makes it possible to add a great deal to the standing charge, as Dr. Hopkinson showed. With regard to equity in tariffs, we must have something to show if challenged by a Government Department or if any given tariff is to be made compulsory. The tariff must have some approximation to equity, but, as Col. Vignoles and other speakers have remarked, it is far better to leave the consumers alone. The maximum-demand system did extremely useful work in the collection of data, but it is impossible to make people understand it and sympathize with it. I think we may say that points of equity as between consumers are not practicable, and we must regard equity only in forming the general scheme for the benefit of the authorities who may criticize it.

Mr. E. W. Cowan: Referring to the paper by Messrs. Wilkinson and McCourt, on page 847 the authors say that the consumer will use every means not to exceed his agreed demand, and on page 849 they refer to the strong incentive to the consumer to decrease his demand on the station. Are the authors quite certain that they would gain an advantage by preventing these excess units being used and paid for by the consumer? If he will still use the same number of units, and use them within his maximum demand, then the advantage is quite obvious; but will he do so? When there is full load on a plant or main, the excess units taken by consumers would be unprofitable to the supply station. The situation seems to call for a means of preventing these units being consumed when the system is fully loaded, and only then. If this view is correct, the question arises as to whether the authors' device can be modified to produce that result. If the device were fitted with a potential coil instead of a series current coil, and adjusted so that the change-over took place at a critical predetermined pressure, which pressure for the particular locality of the consumer would represent full load on the supply mains, then the supply undertaking would be fully protected. That device is not, however, practicable because the consumer whose neighbour is taking an excess demand would be charged at a higher rate than his neighbour, and this might give rise to unpleasantness. If, however, the device could be modified so that without undue complication the series current coil could be put out of action whenever the pressure was above a certain predetermined point, it would solve the difficulty. Quite apart from the economic or practical merits of this suggestion, I am afraid that the authors of both papers would regard it as involving a violation of the principle which they lay down as being the only right principle. I do not agree, however, that the principle laid down is correct. I think that it is scientifically and economically incorrect, and also inequitable. The idea that equal treatment connotes equitable treatment is, I think, fallacious. The authors are mistaken when they attribute to the late Dr. John Hopkinson the principle that the price of electricity to each consumer should be based upon the cost of supplying him, including his proportionate share of standing charges. It was Arthur Wright who enunciated this principle. Dr. Hopkinson's paper dealt with one commodity only, namely, the service of light, and the author said: "The charge for a service should bear some relation to the cost of rendering it." Later in his paper he speaks of a rate having "some sort of relation" to the cost of supply. He was quite alive to the practice of what economists call discriminating between prices, that is the adaptation of prices to market conditions, and he gave in that paper an instance of it, quoting the Post Office as charging ½d. for a circular and 1d. for a letter, whereas the carrying of both cost exactly the same. Dr. Hopkinson was calling attention in that paper to the importance, which is agreed to by everybody, of studying the proper influence of cost upon price, but I cannot find that he advocated that the influence of the value of service should be ruled out. It has always seemed strange to me that no contribution, as far as I know, has been made by any electrical supply engineer which does any sort of justice to the view that both factors should be recognized and allowed for in prices. A leading article in the *Electrical World* to which I referred to-day contained the words: "In order to stimulate demand at varying hours and in various quantities, the rates for electrical service should be based upon other conditions than the cost of service alone. The value of service, together with other conditions, should be taken into careful consideration when rates are made for different classes of consumers," and so on. There is a very large body of people who agree with that view. Such men, I think, form the great majority amongst those who are responsible for the administration of a public utility. All the railways of the world base their rates upon the influence of both factors, and so do all shipping lines. I would beg the authors of the papers to dismiss from their minds that there is any inequity in paying regard to the value of service, that there is any penalizing or subsidizing process accompanying its consideration, or that there is any theoretical unsoundness in it. It seems to be a pity that in our great industry a serious point of view, widely held and adopted in public service, should be treated with inattention and disregard.

Mr. J. W. Beauchamp: The two-rate meter proposed by Messrs. Wilkinson and McCourt does not appear to find favour with previous speakers, but I think that this is because the discussion has centred round domestic supply. Vast as that field is, there are a great many other supplies, and I think that the invention will be useful for certain of them. I do not know whether it will be of service for the household because I believe very strongly that we must sell electricity on the simple multi-part tariff. We can only make such a tariff a success by maintaining high alternative flat rates. A good deal of attention has already been given to whether these multi-part tariffs should be made compulsory or not; the general feeling has been that they should not be, and therefore they need the support of a fairly high flat rate and good salesmanship. Those who are selling electricity for lighting at extremely low rates are doing almost as much harm to the development of this industry as those are who are selling it at extremely high rates. It

makes it quite impossible in the district to push multi-part tariffs, and it generally means the frittering away of valuable surpluses which could be spent on development work.

Mr. Sayers particularly refers to cost. I feel that when we touch this great domestic load, that is to say, when we are dealing with thousands of small premises, we cannot talk about the cost of supplying the individual consumer, because there is no such thing; it varies from moment to moment or from day to day with the other consumers. The tariffs for big consumers are based on the cost of power. This, however, is not done by law, but by competition; it is the only way to compete with gas or coal or private plants. I am in full agreement with Mr. Cowan's statement about the value of the service; it is a perfectly good way in which to sell anything, and I see nothing in the law which prevents it. The law only asks that we should be reasonable as between those in somewhat similar conditions. We are very apt, in making a tariff, to lose sight of this. No difficulty arises when we sell electricity for lighting and power, but when we begin to apply electricity in a large way for heating and cooking we are faced with the fact that the physical yield of 1 kWh of energy to any individual may be so different. A unit gives him a certain amount of light which is very cheap to him at 6d. It gives him 1 h.p.-hour for his motor, which he may be very pleased with at 2d.; but when he wants to cook a dinner he finds that 3 units are required, and the unit may have to be sold at 1d. in order to compete with gas. This seems to me to point to the fact that we must have multi-part tariffs for a long time to come. If one wishes to sell all units at the same rate one must also have some kind of rental or fixed charge. None of the present methods of assessing this fixed charge are, however, free from objection, and it remains to choose the best method and adhere to it.

I do feel there is a field for such a device as that of Messrs. Wilkinson and McCourt, and I also feel that analytical papers like that of Mr. Sayers are valuable. We do not want to get too unscientific. We want to feel that we have behind us the theories of Hopkinson and other investigators; but in order to sell electricity we must have the very simplest tariff. We can offer light and power at a medium price, but we must have competitive rates for heating, and I maintain that we can generally afford to give those rates if only we get sufficient business.

Mr. R. O. Kapp: I think that the line of investigation which Mr. Sayers has taken is of the greatest importance to the supply engineer. I do not think we should underrate the importance of finding out exactly what an individual consumer costs us. But when we have done that, what is the moral we are to draw from the facts and figures we have elucidated? It seems to me that though it is necessary to know what each consumer costs we need not always adjust our tariff accordingly. The purpose of a tariff is not to dole out justice all round, but to do business; I would say to do business with at least a small profit attached to it, and if one devises a tariff to meet those conditions one has really done the best for everybody. The two-part tariff is necessary for those large power consumers whose supply involves a large turnover with a small profit. The charge must be at the rock-bottom price the supply undertaking can afford, and a flat rate at such a price to a large consumer with a lower load factor than had been allowed for might land the supply undertaking in the bankruptcy court. That is really a justification for a two-part tariff. I can never understand, however, in the case of the domestic consumer, whose rate, after all, covers so large a margin for contribution to the overhead charges, what gain there is in a two-part tariff, or in any method for limiting what he buys. So long as his charge is so arranged that at any load factor he is paying not only the net rock-bottom cost but also some sort of contribution to the overhead charges, he is a desirable consumer. Therefore it seems to me that the flat rate which will be low enough to guarantee this condition at the lowest load factor likely to occur will meet the case best.

Mr. F. W. Purse: My objection to the meter proposed by Messrs. Wilkinson and McCourt is that it will switch over from the low rate to the high rate at any time. If, however, the Brockie-Pell patent, by means of which very high-frequency current can be superimposed on the ordinary supply, were to be adopted, it would be possible to switch the meter over from the low rate to the high rate when required. This could be done during the peak, after which the meter could be switched back on to the low rate. With regard to Col. Vignoles's suggestion that we should have no more papers on tariffs, I am never one to say I know everything, and I should like a repetition of papers on tariffs if only to give us the opportunity of examining the question afresh. I do not think there will be any disadvantage two or three years from now to hear someone else's ideas after studying the matter from another angle.

I think that Mr. Sayers has done well to call attention (on page 851) to the four different classes of consumers. Later in the paper he refers to the cost per unit sent out as being the only fair basis for economy. I have for many years always taken my comparison of costs at the station on the cost of units sent out or of the units delivered to the feeders. On page 855 he says: "Many of the two-part tariffs are difficult to justify on any logical ground." He includes in those various tariffs a kilowatt rate, yet on page 854 he says: "But the kW figure for this item of charge should be the number of kilowatts of declared or connected load, not the estimated or observed maximum demand." These two statements appear to be contradictory. At the bottom of page 855 he says: "The practical application of the method which the author suggests for arriving at tariffs for domestic supply is, first, to classify consumers by their load and diversity factors." This, however, would be very difficult to do, and would give rise to a great deal of trouble. The multi-part tariff is undoubtedly the ideal tariff, but I agree with Capt. Donaldson that the best in order of fairness is the installed capacity, that is per 50-watt lamp. My principal difficulty is the initial cost of the installation to the consumer. I am trying to get powers so that when a prospective consumer, no matter whose house it is,

wants an installation I can supply it, and I wish to be empowered to enforce the charge for the installation in that house so long as electricity is used, irrespective of whether the original tenant is in residence at the time or not. As things are at present, if we put in an installation for a consumer on hire terms and he leaves, the next tenant may say: "I did not make the bargain. I am not going to pay you," and as we have no power to enforce the charge we have to remove the installation. I think that the two-part tariff based upon the size of the installation is proceeding on the right lines, and that it is very necessary for the development of the domestic supply.

Mr. F. Gill: It is sometimes possible to obtain useful information from another business. I cannot throw any light on this subject from the lighting point of view, but I think that I can say something of interest from the telephone point of view. The consensus of opinion in regard to telephone costs is that analysis of costs is very necessary and very desirable, but that such analysis of costs does not determine the tariff. The way in which it is done in the telephone business nowadays is somewhat as follows. The load is studied and the way in which it varies is discovered. (Remember that the telephone business has just as many kinds of consumers as the electric supply business, if not more.) Having done that, many schedules of rates are drawn up; in some cases 8, 12 or 15 schedules are prepared. These must be checked against the total installation in order to discover whether they will produce the money required to run the business properly. Those different schedules are then analysed and criticized in quite a number of different ways. They must be simple, the public must be able to understand them, and they must be harmonious in themselves. They must be attractive to the public, otherwise they will not serve their purpose. They must encourage business, and they must be reasonable. At this stage of the examination a number of the tentative schedules have been discarded, and one or more remain which satisfy all those other points which have been raised in the discussion—for instance, what the traffic will bear and how the public will regard the tariff—and one can be chosen which will enable the business to grow.

Mr. P. Rosling: I wish to speak from the point of view of a consumer. I agree with a previous speaker that it is very desirable to have the lighting and heating on separate circuits. Over many years' experience I have not experienced much trouble owing to the lighting fuse going, but my heating fuse has blown on a number of occasions, so that if the lighting and heating circuits were on the same fuse I am afraid the average person would find himself too often in difficulty. I suppose that, with two circuits two meters would be necessary, and this would increase the connecting-up cost, but perhaps that could be overcome in some other way. Many years ago I went into the question of the relative value of gas lighting and electric lighting and, after taking out very carefully my costs over 9 years for running a small plant of my own, including depreciation, I came to the conclusion that electricity had cost me about 7s. a unit. My brother-in-law, who started housekeeping about the same time as I did, had gas in his house, and over 9 years his bills for gas and keeping his house clean were within 1 or 2 per cent of what I paid for the same purpose, and he paid 3s. 6d. per 1 000 cub. ft. for gas. I say therefore that the equivalent value was 3s. 6d. for gas and 7s. per unit for electricity, using fish-tail gas burners and 4-watt-per-candle-power electric lamps. I have always wondered why such a low price is charged for electricity for lighting, because there is such an extraordinary margin in comparison with other systems of lighting private houses. It might actually have been better for the industry if higher prices had been charged, and more energy put into the obtaining of customers.

Messrs. G. Wilkinson and R. McCourt (*in reply*): The discussion has shown conclusively that in the minds of electrical engineers there is no certitude that the best tariff for selling electricity has yet been devised. No attempt has been made to disprove or controvert the statement that a two-part tariff is the most successful in encouraging an increased use of the supply, and that the first part of the tariff—the fixed charge—should be based on the electrical demands of the consumer, instead of upon rateable value, floor area, and other irrelevant bases at present in use. To assume that a consumer's lighting requirements only should be taken as his maximum demand is an idea which should be abandoned; the time is rapidly approaching—if not already here in many places—when the lighting demand and output will be only a small proportion of the total demand and output. To allow the daily peak load to dominate the consideration of tariff problems so much as it has done leads to unsound conclusions; rather we should visualize and prepare for the time when the load factor of the station will be such as will make the peak substantially less important relatively to the total output. Supply undertakings are too ready to tell consumers at what hour of the day they should take a supply. The general public want to use electricity just when it suits them, as they do any other daily necessity, and a tariff which lends itself to this end, without the intervention of expensive time clocks and complicated book-keeping, is the one that will ultimately prevail and displace present-day complications and unjust tariffs. These characteristics we claim for the uniform tariff.

Before summing up we will deal with some of the specific objections levelled against the system during the discussion.

Colonel Vignoles states that discussion on tariffs is not required, but he withdraws this statement later as a result of his more detailed investigations. Surely, the fact of the Government appointing a Committee to consider and report on the question of tariffs is conclusive evidence that the standardization of tariffs is a prime factor in future development; therefore any paper or discussion by electrical engineers that assists this object is both desirable and beneficial. The Wright system is characterized as a complicated system, but its equity is not challenged. True it is difficult to explain to the layman, but the uniform tariff meter which we advocate renders this explanation unnecessary and the consumer knows in advance exactly what number of units he has to pay for at the initial high figure to cover standing charges; he also knows that

the units consumed beyond this figure are secured at such a cheap rate that he can afford to use electricity for all purposes and realize all the convenience and advantages it is capable of conferring. As stated in the paper, the consumer is not switched into the third rate except when he deliberately decides to do so for reasons of his own; and although this third rate is put as high as 6d., in actual practice 3d. or 4d. per unit would probably be the maximum price. The claim that "we must have a tariff by means of which a consumer can be charged according to the readings of a single meter" is precisely what we are proposing, namely, a meter of extremely simple and reliable construction without time clock or other contraptions so often used in connection with two-part tariffs to-day, which place undue restrictions upon the consumer and incur heavy supervision, repair and maintenance charges on the supply undertaking. We are credited with the intention of putting existing consumers on the uniform tariff, scrapping their old meters and imposing upon them additional expense for uniform-tariff meters. We have made no such suggestion and disclaim any such intention; it is in the new areas and to new consumers that the modern meters and methods would be offered as an alternative to existing tariffs. Old customers would come in by degrees when the new meters and tariff demonstrate their economy and superiority, as they would do in a comparatively short time. This will ensue without special effort on the part of the salesman, a few favourable comparative results being much more effective in business-getting than the special pleading of plausible salesmen. Colonel Vignoles is content to depend for increase of business upon expert canvassers advocating possibly inequitable tariffs; we prefer an equitable tariff which, while holding existing business, is attractive enough to secure the additional business which present tariffs do not attract.

Captain Donaldson's criticisms are generally fair, having in mind "the state of the art" as it is commonly known to-day. The full significance and value of uniform tariffs will not be realized until simple means are provided enabling consumers to take electrical energy during periods when at present there is negligible demand; in other words, until the load factor is greatly increased in each individual case. It is recognized that in an all-electric house the number of units consumed will be many times that in a house equipped for lighting, the usual electric iron, vacuum cleaner, an electric radiator or two for occasional use and, say, a breakfast cooker. The all-electric house calls for electric heating all day long for at least eight months in the year, the amount varying according to the weather; it demands supply for cooking every day and a generous supply for water-heating purposes. This all-electric demand means an increased consumption per house, of 5 to 10 times the present-day average. With present-day methods this supply is not commercially attainable. Fortunately, however, the major portion of the demand, is for the production of "low grade" heat, viz., say, half the cooking and all water and room heating. Low-grade heat can be efficiently and cheaply stored, and for this purpose the consumer can take electricity during hours when there is at present none or very little electricity being used. Herein lies the possibility of attaining a 50–75 per cent load factor in place of the present average of 22–25 per cent. Careful investigations reveal the fact that the second 25 per cent increase in the load factor, viz. from 25 per cent to 50 per cent, can be generated and delivered to consumers on existing mains at about one-sixth the price per unit of the first 25 per cent and sold with profit at about one-quarter the average cost. To describe this method in detail is outside the scope of this discussion, but in the near future such off-peak storage radiators, water heaters and cookers will be available. A due proportion of these will, by simple and reliable means, be cut out of circuit during the consumers' heavy demand hours for other purposes and come on again when that demand is reduced. Approximately half the cooking and the whole of the water and room heating can be done with these off-peak devices; thus they will keep the consumer's maximum demand low, protect him from the penalizing dial of his uniform-tariff meter, and give him the benefit of the low costs of production due to the load factor being increased from 25 to 50 per cent. This may appear a highly imaginative piece of prophecy, but it is nearer realization than may be supposed. Such pending development is bound to have marked effect on the cost of electricity supply for all purposes, especially upon tariffs, and yet we are told with unusual confidence and emphasis that the "tariff problem is settled" and that discussion upon it should be banned by the President. Possibly rather than banning discussion the Institution may afford an opportunity of enlarging upon the possibilities of these off-peak storage supplies at a later date. The two-rate meter and uniform tariff we have ventured to advocate will then be better understood and appreciated.

Somewhat scathing reference was made in the discussion to our advocacy of the use of storage batteries deriving their charging current during the hours of light load and discharging their current on heavy load, thus keeping down the maximum demand and thereby reducing the fixed capital charge. The proposal was referred to as a "horror" and accumulators as "messy batteries," the experience of amateur wireless operators being alluded to as confirmation. To apply such a method in the case of small consumers would obviously be absurd, but in Harrogate two of our largest consumers have employed this method for over 20 years with outstanding success and satisfaction to all concerned. Another large consumer of long standing is introducing the system at present. We therefore consider the recommendation made in our paper to be quite sound and amply justified by long experience.

With the off-peak storage methods already briefly referred to, Mr. Cowan's ingenious but difficult refinements are not called for and his demand for a means of preventing these (extra) units being consumed when the system is fully loaded is entirely met.

Mr. Purse's proposal for control by means of "ripple" currents in the distribution system also loses its significance, as every consumer with an all-electric establishment and off-peak heat storage will himself provide the long-hour advantages and characteristics. Under present conditions of the industry these are attained to a limited extent only, by taking on a large number of

consumers each using current for different purposes during varying times of the day, but who individually are non-users for many hours out of the twenty-four.

Mr. H. M. Sayers (*in reply*): The discussion brought out two principal criticisms of the proposals of the paper. The first is that the " value of service " should be taken account of in tariffs, as well as the cost of supply. The second is that a two-part tariff is easier to formulate, easier to apply, and easier to sell on, than a series of flat-rate tariffs based on the classification of consumers' loads. The first criticism involves general principles. Any commodity or service can only be sold to any individual consumer at a price which the consumer considers to be not in excess of its value to him. The money value of any service or commodity varies greatly as between different consumers and classes of consumers, and the price which anyone will pay depends also upon what he can afford.

Domestic electricity supply is a service the value of which cannot be assessed completely, or even approximately, in terms of money. Cleanliness, comfort, healthfulness, convenience, adaptability, relief from drudgery, are all " values " which cannot be put into money terms; every one is willing to pay some money for them; but the great majority of potential domestic consumers can only pay some limited amount. The people who will obtain the greatest values in this sense are precisely the people who can afford the smallest payment. The wage-earner with a young family whose wife is the mother-housekeeper will get a greater value in comfort, general happiness and relief of drudgery from an all-electric house than the middle-class householder whose means permit the keeping of two or three servants; but the former can afford to pay less for the service.

The price obtainable from any domestic electricity consumer is his own valuation of its advantages compared with alternative means of obtaining the same primary service. This price is not susceptible to calculation by the seller on any principle whatever; therefore I say that the " value of service " basis is not available. A striking instance of this was given by Mr. Rosling's contribution to the discussion. Electric lighting, he said, was worth 7s. per unit to him in clear money terms (saving on house decorations, etc.), a price at which electric lighting could have made no progress at all. Nor could the most persuasive salesman have persuaded one possible consumer in a hundred thousand that any such result was other than the figment of a lively imagination.

A commercial price must exceed the bare cost of supply by the increment of profit which is necessary to remunerate the capital engaged. Such a price will result in the largest profitable sale; for clearly the potential consumers who cannot or will not pay so much are not accessible excepting at a loss; whilst all those who can and are willing to pay that price are accessible. It is true that some of these may be willing and able to pay a higher price, but such higher price will shut out a larger number and probably increase the unit cost. I maintain that the value of service to different classes of consumers cannot be ascertained, but that the cost of supply to such different classes can; it is therefore the practicable basis for fixing tariffs. The differentiation is the proportion of the different purposes of connected load, and the ascertainment is by observation of a sufficient number of cases with similar proportions.

As to the preference generally expressed for two-part tariffs, the following comments are offered: It is admitted that the periodic fixed charge, per annum or per quarter, is intended to represent the fixed-charges element in the cost of supply. It ought, then, to be based upon some feature of the consumers' demand which corresponds to that cost. So far as I can discover, this is not the case in any of the usual two-part tariffs. The favourite rateable-value basis is not defended by anyone as having any necessary relation to the fixed-charges cost of supply. It is therefore not necessary to show that it is a purely empirical basis. It is easy to apply, but the consequences of periodical rating revaluations may cause trouble. It is clearly not equitable. Maximum demand is a fair basis as between consumers having similar load characteristics and some definite diversity factor, not as between consumers with different load characteristics. It is ruled out for that reason; but it is the principle I propose to use, for *each class* of consumer, without the complication of instruments and calculations for individual consumers.

It is said that two-rate tariffs are easier to sell on than a series of flat rates. That depends on the salesman. To sell domestic supply the salesman should advise the potential consumer what he ought to install, and after discussion settle with him what he will have. Then he can quote the appropriate flat rate. Any number of the rates can be quoted, but each in relation to defined proportions of consuming apparatus, lighting, cooking, etc. Such a method of salesmanship will get a better aggregate class of connected load than quoting a rateable value or other irrelevant periodic charge and a rate per unit, regardless of the class and proportion of the apparatus installed.

The charge by classification does not exclude two-part tariffs. The fixed-charges elements in the cost are definitely evaluated by the plan I propose. If it seems better to separate them and levy them by periodic payments it can be done, with the advantage that the amounts are related to the average demands on the system by that class of consumer. Alternatively each consumer may be charged at a high rate for a fixed number of units per quarter, and a low rate for the remainder, the fixed number depending upon the character of the connected load and its magnitude.

The great objection to two-part tariffs for domestic supply is that a large proportion of potential consumers are not able or are not willing to engage to make relatively large quarterly payments. Many of them pay weekly rents; many find rents, rates, and other quarterly payments quite enough to pay in lump sums. To this large proportion of potential consumers the most attractive method of payment is by prepayment meter; and I suggest that generalized domestic electrification depends ultimately upon prepayment-meter methods, which necessitate flat rates; or, alternatively, upon weekly collection, which is too expensive and cumbersome.

I would repeat, with emphasis, that on the selling side the supply industry has to raise system load factors from the prevalent level of between 20 and 30 per cent, to the quite possible level of between 45 and 60 per cent—excluding traction and chemical loads. The field open is that of domestic supply. The method—so far as it depends upon price—is to fix prices in relation to costs, i.e. to load and diversity factors by classes.

I am disappointed at the absence of discussion on the subject of distribution economy illustrated by the table and figure in the paper. It is a subject intimately connected with tariffs, for low rates require low distribution costs; low distribution costs involve good distribution load and form factors; and good distribution load and form factors can be secured only by tariffs which stimulate and by salesmanship which obtains loads of the right character. As Mr. Beauchamp said, "Put down heavy copper and fill it up." But fill it up in time, as well as maximum load. Distribution design for total economy is not a common feature of supply undertakings in this country. It has been a hand-to-mouth process generally. Certainly it has been very difficult to forecast the growth of load both in time and in space. There is evidence that the hand-to-mouth policy persists; and that in many places new distribution work is in progress which cannot give economical results. With effective tariffs for domestic supply it should soon be possible to calculate loads as closely as the water-supply engineer can calculate water consumption and the necessary mains. At this stage of development, distribution should be designed for maximum economy for a reasonable time ahead, just as telephone systems are. The problem is simpler and the risks of mistaken forecasts smaller.

Turning to some individual criticisms, I note that Colonel Vignoles admits that his first impression that discussions on tariffs are inopportune has been corrected by statistics. I suggest that he might usefully reconsider domestic tariffs. His undertaking has the creditable load factor of 35·72 per cent, exceeded by only five undertakings in the current *Electrical Times* list. But, first, he has a tramway supply, and secondly, the sales for private supply are only 80·5 units per head of the population per annum. There is room for improvement. Colonel Vignoles has certainly led his Council in the right direction in respect to domestic supply. I am sure he wishes to go further.

Captain Donaldson (with others) thinks that the high initial rate corresponding to the fixed-charges cost must be based on the lighting demand. I am not sure of this, even now. With generalized domestic electrification the house lighting load is likely to become a mere pimple, and it may not be on the domestic peak at all. Sunday mornings will probably see the domestic peak. Shop lighting, factory lighting, and street lighting are in a different category. Captain Donaldson says that it is useless to attempt to base a demand charge on the cooking and heating load, "because no one knows how it will work in practice." I say: Find out how it works in practice, by observing a sufficient number of consumers to give a fair average. With that knowledge, the base is given. Such tests may possibly show that the lighting connections give a good basis, with a proper multiplier for each class; but I doubt it as a permanent relation.

Mr. Blaikie thinks that I overrate distribution costs (not the "cost of mains") compared with generating costs. The President gave a similar ratio in his Address at the beginning of the current session. I have found such relative costs in many analyses which I have had to make for separating the two classes of costs. Mr. Blaikie has perhaps not noticed that the cost of "units unaccounted for" is a distribution cost which appears in the station expenditure. Distribution costs are even more susceptible than generation costs to diminution by improved load characteristics, but it must be improvement all over the system.

Mr. Cowan quite correctly credits Arthur Wright with the enunciation and application of the principle of charging consumers upon their cost. It was in a paper read before the Municipal Electrical Association at Brighton in 1896. Wright's pioneer work cannot be overrated. It is the basis of every rational tariff. His name is much more generally attached to such tariffs in the United States than in his native country. I very much regretted his absence from the meeting. He could have given some interesting information about supply tariffs in the United States, where the subject is very much alive and the multiplicity of tariffs is relatively as great as it is here.

Mr. Beauchamp is right in saying that we cannot talk about the cost of supplying the individual domestic consumer. But we can find out the cost of supplying classes of similar domestic consumers, and use the averages with such loading as seems prudent, exactly as insurance companies adjust premium rates by ascertained averages. He agrees that none of the present methods of assessing the fixed charge are free from objection. I propose to assess it by trial. Whether it is levied as a periodic fixed charge, a high rate for a minimum consumption followed by a low rate, or a flat rate, is a matter of expediency and detail.

I am grateful to Mr. Kapp for his agreement.

Mr. Purse, I think, really agrees with me in principle, for the power he hopes to get will surely include some way of adjusting the charge to the class, in the sense of proportion of kinds of load, as well as the size of installation. Mr. Purse thinks that there is an inconsistency in the paper, overlooking that on page 854 the item of charge on the connected load is only that fraction of the fixed charges to cover the cost of the individual service, meter, etc. Mr. Purse alludes to the very important matter of the supply of apparatus to the domestic consumer. That is correlative to the matter of attractive domestic tariffs, and just as essential to general domestic electrification. But it is not the subject of the paper.

With Mr. Gill's remarks I am in complete agreement. The experience of a comparable industry is most useful.

Mr. Rosling sets out some quite sound reasons for separating lighting and heavy-current circuits. I have already referred to his statement on "value of service."

In conclusion, I would thank all contributors to the discussion, the value and interest of which is ample reward for starting it. The initiative of the Council in arranging for it is most opportune, in view of the developments in immediate prospect.

THE USE OF INDUCTION REGULATORS IN FEEDER CIRCUITS.

By Laurence H. A. Carr, M.Sc.Tech., Member.

(*Paper first received* 8*th November*, 1924, *and in final form* 1*st January*, 1925; *read before the* North-Eastern Centre 26*th January*, 1925.)

Summary.

The paper describes the uses and possibilities of induction regulators as applied to feeder and interconnector circuits.

Three types of induction regulator are described, together with their characteristics; the single polyphase regulator, the double polyphase regulator, and the single-phase regulator.

The application of regulators to various types of circuit is considered, first to the supply feeder, secondly to the interconnector between power stations, and then to the ring main or twin feeder.

The effect of regulator impedance is discussed.

Finally, the operation, construction, and control of induction regulators are discussed.

Introduction.

The function of the induction feeder regulator is to provide an additional pressure in an alternating-current feeder, either for raising the voltage at the far end of a simple supply feeder, or for controlling the power factor and in that way assisting the transference of power along a feeder connecting two or more generating stations.

In the United States it is very largely used for this purpose and with the growth of large supply systems and large interconnected groups of systems its use is increasing in this country. It is important to possess a clear knowledge of the characteristics of the induction regulator before laying down the requirements for any given circuit, and it is to discuss the behaviour of the induction regulator under different conditions that this paper has been written.

In general three types of regulators may be considered for use with alternating-current feeder circuits:—

(*a*) The single polyphase regulator.
(*b*) The double polyphase regulator.
(*c*) A bank of single-phase regulators.

The Single Polyphase Induction Regulator.

The polyphase induction regulator is similar both in construction and in theory to the three-phase induction motor at standstill. Such a machine has the characteristic that, depending on the position of the tappings of the secondary coils relative to the tappings of the primary coils, any phase displacement between zero and 360° may exist between the E.M.F. produced by the secondary and the E.M.F. supplied to the primary.

The regulator normally works at standstill, but one part (either the primary or secondary, as may be most convenient) is made to rotate relatively to the other so that any desired phase displacement between the two parts may be obtained from full arithmetical sum to full arithmetical difference. The secondary windings are provided with two terminals to each phase-winding and are connected in series with the line as shown in Fig. 1, the connection being somewhat similar to that of an auto-transformer.

Fig. 2 shows the vector diagram of the voltages (only one phase being shown for clearness), where OA

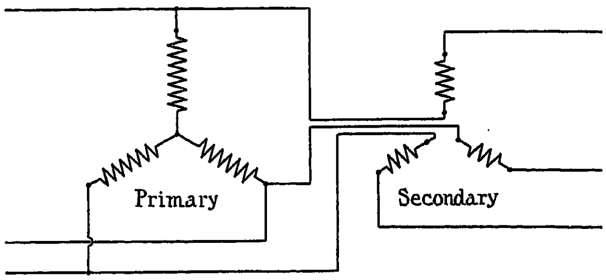

Fig. 1.—Diagram of connections of induction regulator.

is the supply voltage, AB the secondary induced voltage, and OB the resultant is the outgoing voltage applied to the feeder. In this diagram, and in all the succeeding diagrams except Fig. 17, the impedance-drops in the regulator, which are relatively small, are neglected.

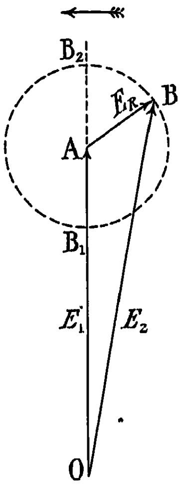

Fig. 2.

The locus of B as the rotor is turned round is a circle with A as centre, and the complete circle corresponds to a movement through two pole-pitches. The limiting values of OB are OB_2, the maximum positive boost, and OB_1, the maximum negative boost.

In practice it is sufficient to move the rotor through one pole-pitch only in order to obtain the full variation

between OB_1 and OB_2, the vector AB travelling either round the trailing semicircle or the leading semicircle shown in Fig. 2, and in general either semicircle can be selected by suitably relating the motion of the rotor to the phase rotation of the primary.

Apart from the magnetizing current and losses of the regulator, the kVA input is equal to the kVA output, and the power factor of the primary circuit is the same as the power factor in the secondary winding of the regulator, which, it should be noted, is usually not the same as the power factor of the feeder circuit, since the E.M.F. induced in the secondary winding is usually not in phase with the line pressure.

This may easily be understood by reference to Fig. 3, the full lines being first considered. Here E_1 represents the supply voltage, E_R the secondary voltage of the regulator, and E_2 the feeder voltage. I_2 is the feeder current at an angle ϕ behind E_2.

The power generated in the secondary windings of the regulator is the vector product of E_R and I_2.

Apart from the magnetizing current, the primary ampere-turns in the regulator must balance the secondary ampere-turns, exactly as in the case of the induction

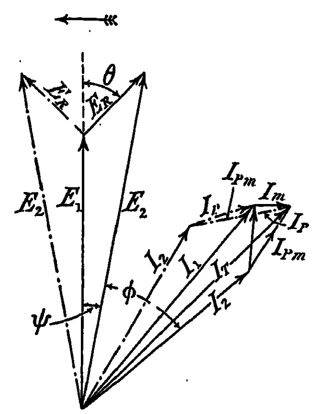

FIG. 3.

motor, and for the same reason, but the ratio of turns is given by the ratio of voltages E_R/E_1. Hence the corresponding load current I_P taken by the primary will be in magnitude equal to $I_2 \times E_R/E_1$ or, in other words, the primary kVA equals the secondary kVA, neglecting the magnetizing current and the losses in the regulator.

The primary kW must equal the secondary kW, therefore the primary power factor equals the power factor in the secondary winding. In other words, if E_R lags behind E_1 by the angle θ, then I_2 lags behind I_P by the angle θ. These considerations enable the primary current I_P and the total current supplied, I_1, to be drawn, the magnetizing current still being neglected.

The two triangles E_1, E_R, E_2 and I_2, I_P, I_1 may then be considered. Since $I_2/I_P = E_1/E_R$, and the angle between I_2 and I_P is the same as the angle between E_1 and E_R, namely $(180 - \theta)$, the two triangles are similar and the two angles at the origin are the same. Therefore the angle of lag between I_1 and E_1 is identically the same as that between I_2 and E_2.

It will be noted that there is a phase lag (angle ψ in Fig. 3) between the E.M.F. on the two sides of the regulator, but the same phase lag exists between the two corresponding currents.

Returning to Fig. 2, it is seen that the same boost could be obtained with the secondary voltage E_R leading E_1.

The chain-dotted lines in Fig. 3 give the corresponding diagram for this alternative position of the regulator giving the same boost.

Including the magnetizing current of the regulator, the total primary current of the regulator I_{Pm} consists of the vector sum of the load current I_P and the magnetizing current I_m, while the total current taken from the supply is I_T, the vector sum of I_2 and I_{Pm}.

It will be seen that the regulator primary current I_{Pm} is not the same for the two positions of the regulator giving the same boost, although the total supply current remains the same. This may appear to be unexpected, but consideration shows it to be due to the fact that the alternative positions of E_R do not and cannot (except at times of maximum boost) make the same angle with I_2, and hence the power factor in the secondary winding of the regulator is different in the two cases. The induction regulator may be further studied by means of a locus diagram (corresponding to the induction-motor circle diagram) showing the variation in the current input at varying loads. Unlike the case of the induction motor, however, a single curve does not suffice unless the conditions under which the regulator is working are laid down, that is to say unless the relationship between the amount of boost and the load current is specified, and the power factor of the feeder current fixed.

In any case, however, the diagram centres round the maximum boost conditions (in which case the two alternative diagrams shown in Fig. 3 become identical).

At maximum boost, with a given angle of lag ϕ in the feeder circuit, the input current may be represented by a line such as PN in Fig. 4 (*a*), composed of two components, PM the magnetizing current, and MN the component equal and opposite to the secondary current multiplied by the ratio of turns.

PE is the applied primary voltage, and MN is inclined at the angle ϕ to PE. Three cases may be considered, corresponding to the three curves drawn in Fig. 4 (*a*).

In each of these cases the feeder power factor is assumed to be constant and the regulator impedance is neglected. In case I (curve I in the figure) the feeder current is assumed to be constant irrespective of the amount of boost. Here the locus of N is a circle, the full circle corresponding to a movement of the rotor through two pole-pitches. The angle θ between MN and any selected position of current MN′ gives the mechanical angle (measured in electrical degrees) through which the rotor must be displaced from the maximum boost position in order to give the conditions represented. This case is seldom, if ever, met with in practice, but the curve is of use, as it gives a comparison of the input required for the same output in kVA at different power factors, since it serves to show the variation in the position of MN with various values of ϕ if the angle θ remains zero.

In the second case, represented by curve II in Fig. 4 (*a*),

the boost required is assumed to be proportional to the feeder current. If the angle ψ in Fig. 3 is small the boost is practically equal to $E_R \cos \theta$. If this equality were absolute, the resulting curve would be a circle on MN as diameter, and it is shown as such in the figure, since the distortion introduced due to the angle ψ is exceedingly small. This diagram corresponds to an interconnector regulator capable of transmitting the feeder current in either direction, in each case supplying the necessary pressure to overcome the line pressure-drop. Since the current reverses at zero boost, the circle on MN as diameter is swept out twice for a regulator movement through two pole-pitches. The boost corresponding to any given current can be quite simply determined by drawing the voltage diagram in a particular manner alongside the current diagram, as illustrated in Fig. 4 (*b*). It will be noted that in this diagram the rotation of the vectors with time is clockwise, that is to say in the contrary direction to Fig. 4 (*a*). The feeder current is drawn vertically, OI representing the current at maximum boost. The supply E.M.F. (OA in the diagram) is therefore parallel to MN in the current diagram. For any position of the current vector, say along MN′, it is only necessary to draw the regulator voltage AB parallel to MN′ to give the E.M.F. supplied to the feeder, namely OB.

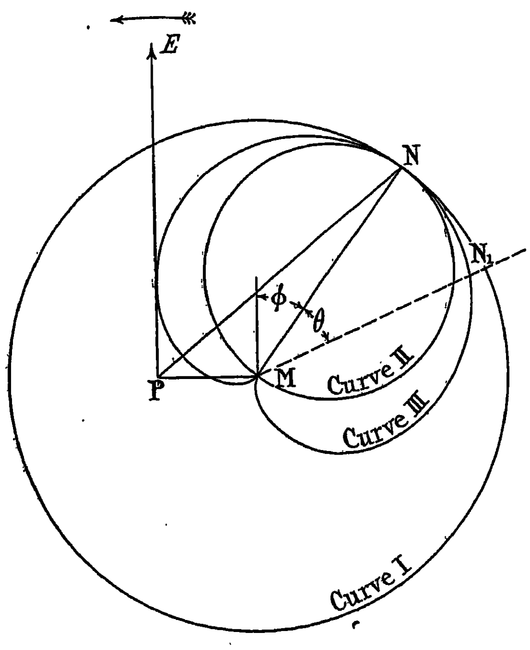

Fig. 4 (*a*).

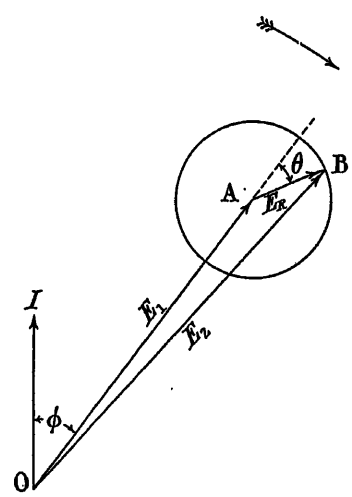

Fig. 4 (*b*).

The third case considered, curve III, represents the case where the transformer or other supply ratios are so chosen that the regulator is required to give its full back pressure at no load, the whole range of the regulator being available for raising the voltage as the load comes on. In other words, at no load there is full negative boost ("buck") on the regulator, at half load there is neither negative nor positive boost, and at full load there is full boost. This arrangement gives the smallest regulator for a given supply feeder service. The resulting curve is swept out once as the regulator is moved through two pole-pitches.

In each case shown in Fig. 4 (*a*) as the rotor of the regulator moves from the full boost position the diagram may be swept out in a right-handed or in a left-handed direction, depending on the direction in which the rotor is turned.

Except in the case of an interconnector regulator loaded as described in case II, where the whole diagram is necessarily swept out, it is advantageous to sweep out the diagram in a left-handed direction, since in that case the primary current and hence the primary copper losses are less than if the diagram be swept out in the other direction. This favourable relation is obtained if the rotor is moved from full boost position in the same direction as the rotating magnetic field when the rotor carries the secondary winding, and in the opposite direction if the rotor carries the primary winding. This phasing-out must be checked on site, as it cannot be prearranged at the manufacturer's works, any more than can the direction of rotation of an induction motor, unless the phase rotation of the leads to which the regulator is to be connected is known.

Double Polyphase Regulators.

In certain cases, to be discussed later, the phase-shift between the supply voltage and the delivered voltage (that is to say the angle ψ in Fig. 3) is objectionable. To overcome this defect the double polyphase regulator is used. This consists of two regulators each of half the total capacity, with the secondaries connected in series and arranged so that the phase-shift of one neutral-

izes the phase-shift of the other. The voltage vector diagram of this arrangement is shown in Fig. 5, the regulator impedance being neglected, where OA is the supply E.M.F. and AB_1 and B_1B_2 are the E.M.F.'s of the two halves of the regulator.

As the rotors of the regulators are moved, the vector AB_1 turns in a clockwise direction, while the vector B_1B_2 turns in a counter-clockwise direction. The resultant voltage OB_2 is therefore always in phase with OA, the supply voltage, and varies from OC_2 as a maximum [equal to $OA + (AB_1 + B_1B_2)$] to OC as a minimum [equal to $OA - (AB_1 + B_1B_2)$]. In order to obtain this effect, either the two rotors may be made to rotate in the same direction while the two rotating fields rotate in opposite directions, or the rotors may move in opposite directions while the fields rotate the same way. The former is the more usual in practice.

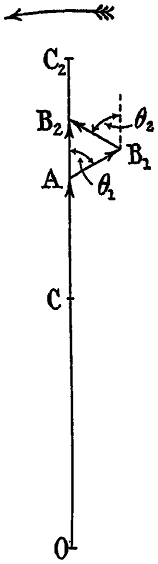

FIG. 5.

In either case, referring back to Fig. 4 (*a*), it will be seen that while one half of the regulator sweeps out the right-hand side of the particular locus diagram concerned, the other half of the regulator will be sweeping out the left-hand side. In other words, for the double regulator one half automatically takes up the most favourable conditions, the other half the unfavourable conditions.

This diagram also shows that except at times of maximum and minimum boost the two primary windings do not carry the same current, and consequently they must be connected in parallel and not in series.

The Single-Phase Induction Regulator.

The single-phase regulator is principally used on single-phase circuits, but may also be used in a bank of three units on a three-phase system. In the single-phase regulator the magnetic field is purely alternating, and as the secondary winding is gradually turned out of the axis of the magnetic field, the E.M.F. induced in it is reduced without any phase lag (apart from that due to the impedance of the windings). The conditions here are thus different from those in the case of the single polyphase regulator, and are more akin to those of the double polyphase regulator.

At the same time, the single-phase regulator has one important characteristic which must not be overlooked in the design, and that is that in the position of no boost, and if no special precautions are taken, the secondary current will induce a very large flux in the regulator at right angles to the main flux. This will cause the reactance of the secondary winding to be exceedingly high, thus forming an impedance in the feeder circuit. To overcome this difficulty an auxiliary winding short-circuited upon itself is placed upon the primary member at right angles to the primary winding. This has the effect of keeping down the reactance in the secondary circuit to a practically constant value.

In a bank of three single-phase regulators, if the load is balanced between the three phases and the regulators are mounted so that each gives the same boost, each primary requires the same current, and hence the primaries may be connected in star. In this case the

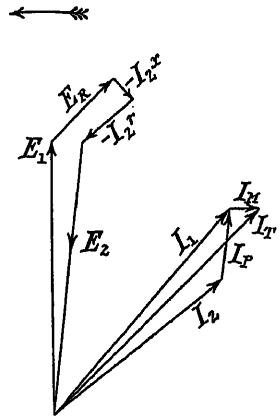

FIG. 6.

voltage induced in the secondary winding will be in phase with the phase voltage and not with the voltage between the outers.

The three regulators can be, and usually are, geared together mechanically so as to operate simultaneously. Owing to the small size of each unit where single-phase regulators are used, and on account of the losses in the auxiliary or damping winding, the efficiency of a single-phase bank is usually lower than that of the corresponding polyphase regulator, while in addition its first cost is generally higher.

Feeder Circuits.

In an ordinary feeder circuit the function of the induction regulator is to provide an E.M.F. to overcome the impedance drop in the feeder in order to keep the voltage constant at the far end.

It is not necessary for this added voltage to be exactly in phase with either the applied voltage or the feeder impedance drop, so long as the outgoing voltage from the regulator is of the correct magnitude. Fig. 6 shows

the vector diagram* of a feeder circuit supplied by an induction regulator, which is shown as giving only about half its maximum boost, in order to emphasize the phase differences. Here E_1 represents the supply voltage, and E_R the regulator voltage, giving the total voltage of E_2 applied to the feeder.

I_2 is the feeder current, I_P the regulator primary load current, I_M the regulator (primary) magnetizing current and I_T the total current supplied from the generating plant.

Interconnector Circuits.

Where two power stations are connected together by a feeder the power supplied by each station will depend solely on the power supplied to the prime movers. Under these conditions, power can be supplied at will from station to station, but if the voltage at each end of the line is to be kept the same, the power can only be transmitted at a low leading power factor. This

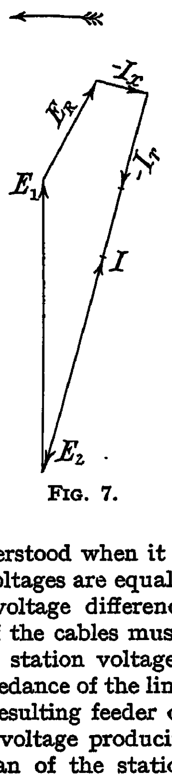

Fig. 7.

may be readily understood when it is remembered that since both station voltages are equal or are equalized by transformers, any voltage difference which can exist between the ends of the cables must be at right angles to the mean of the station voltages. This would not matter were the impedance of the line purely inductively reactive, since the resulting feeder current would be at right angles to the voltage producing it, and hence in phase with the mean of the station voltages. Since, however, the resistance is usually greater than the reactance, the current will be more nearly in phase with the voltage across the feeder, lagging at most, say, 30° behind it (corresponding to a ratio of $x/r = 0 \cdot 578$), which means that the current vector is 60° away from the mean of the station voltages.

Since cos 60° $= 0 \cdot 5$ it follows that the interconnector when fully loaded as to its current is only transmitting half of the power which it should be able to carry. To utilize the interconnector to its full, an induction regulator (or other adjustable boosting apparatus) is required to provide a voltage which will just overcome the impedance drop in the interconnector when the current corresponding to the power transmitted is flowing at the desired power factor.

With an induction regulator, the power factor in the interconnector may be maintained at unity at any load without necessitating any alteration in the voltage of either station. Alternatively, with constant station voltage, the magnetizing current may be shared between the stations as desired (the interconnector being loaded at the corresponding power factor) by adjusting the amount of boost given by the regulator.

Fig. 7 illustrates the transmission of power from station to station where a regulator is installed in the interconnector, the power factor being unity at the receiving end. E_1 is the busbar voltage of the station supplying power, E_2 the busbar voltage of the station receiving power, E_R the regulator E.M.F. (applied at the sending end in this instance), I the interconnector current, and x and r the interconnector reactance and resistance respectively. The regulator primary current is omitted from this diagram.

Fig. 6, which was drawn for the case of a dead-ended feeder, also applies to the case of the interconnector, and represents the transmission of power from station to station at a lagging power factor. In this case I_2 is the current transmitted along the interconnector, while the total current I_T necessary to be supplied by the sending station is also shown. It should here be emphasized that it is only by the aid of an induction

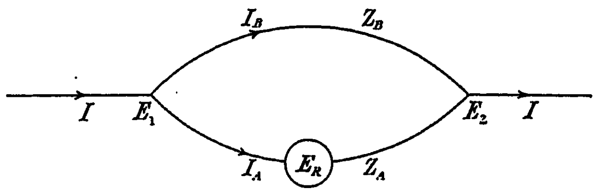

Fig. 8.

regulator or a similar device that the operators in the power stations can have complete control not only of their own voltage and power supply but of the power transmitted from station to station and of the power factor at which it is transmitted. Further, the induction regulator, though expensive, is the only practical device which permits the control to be gradual.

Where there is no other connection between the two stations than the interconnector containing the regulator, the regulator may be of the single pattern since no difficulty is introduced by the fact that one station may slightly lead the other in phase.

Regulators on Ring Main or Twin Feeder Systems.

Special consideration must be given to the case where it is required to insert a regulator in a feeder, the ends of which are connected together electrically by another feeder or system of feeders. The simplest case to consider, which will be used as an example, is where only two feeders supply the same point, feeder A containing the regulator, while feeder B is connected direct to the receiving end without any regulator being inserted, as illustrated diagrammatically in Fig. 8.

* In this and the succeeding vector diagrams the convention is adopted that "the sum of the voltages in a circuit is zero"; consequently an impedance drop is represented by $-I(r + jx)$, while an E.M.F. representing a motoring action, or absorption of electrical power, is in the contrary sense to $I \cos \theta$.

Let E_1 = E.M.F. at supply end.
E_2 = E.M.F. at receiving end.
E_R = regulator E.M.F.
I = total current transmitted = vector sum of I_A and I_B.
I_L = full-load value of I.
I_A = current in feeder A.
I_B = current in feeder B.
$Z_A = \sqrt{(x_A^2 + r_A^2)}$ = impedance of feeder A.
$Z_B = \sqrt{(x_B^2 + r_B^2)}$ = impedance of feeder B.
$\frac{x_A}{r_A} = \frac{x_B}{r_B} = \tan\zeta$

By suitably adjusting the regulator, E_2 may be maintained equal in value to E_1 whatever the magnitude and phase of the current I. It is desired to determine how the total current splits up between the two feeders in these circumstances.

The conditions and the solutions are identical whether the feeder system is dead-ended, supplying power to a load; or whether it links up with the busbars of another station, supplying power to it.

For constant power factor and varying load, if the regulator impedance be neglected, a simple geometrical construction will give the desired solution in the form of the locus of I_A, the current in feeder A, if the power factor is measured with reference to a vector E_M located midway between the vectors representing the voltages of the two stations as drawn in Fig. 7. This gives the solution for the mean of the two cases where the regulator is situated at the receiving and at the supply end of the line respectively. Taking first the case of the single regulator, where E_R is made numerically equal to $I_L Z_A$, the magnitude of the regulator voltage remains constant, but its phase angle is varied as load comes on, in order to meet the required condition that E_2 shall be numerically equal to E_1.

Fig. 9 gives the vector diagram of the E.M.F.'s present and leads to a simple graphical method by means of which the current locus may be determined as follows:—

In Fig. 9 let OA $= E_1$
BO $= E_2$

AB must necessarily be at right angles to E_M.

Then if AC $= E_R$
CB $= -I_A Z_A$ and AB $= -I_B Z_B$.

Extend AB to D and cut off BD such that

$$\frac{BD}{AB} = \frac{Z_A}{Z_B} = \frac{-I_B Z_A}{-I_B Z_B}$$

Join CD
Then CD = CB + BD (vectorially)
$= -I_A Z_A - I_B Z_A$ (vectorially)
$= -IZ_A$

CD therefore always remains parallel to itself for any given case of constant power factor, while E_R moves through the arc of the circle.

By dividing the vectors in this voltage diagram by $-Z_A = -(r_A + jx_A)$, treated as a complex number, that is to say by dividing the numerical values by $\sqrt{(x_A^2 + r_A^2)}$ and turning the vectors in a clockwise direction through the angle $(\frac{1}{2}\pi + \zeta)$, where ζ = arc tan x/r, the current diagram (Fig. 10) is obtained, where the line CD representing the current I corresponds to the line CD representing $-IZ_A$ in Fig. 9.

To find the current conditions for any given load I, the circle of radius E_R/Z_A must be struck and the line

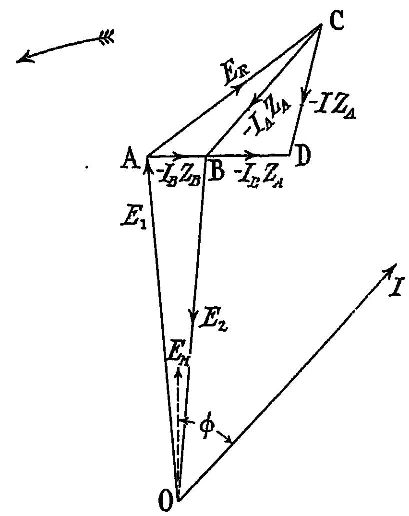

FIG. 9.

$(I_B + I_B Z_B/Z_A)$ drawn from D, the termination of I, making an angle of ζ with the horizontal axis. This line must be cut off where it cuts the circle at A, and DA divided at B in the proportion Z_A/Z_B as shown in Fig. 10. This point B gives the position of the end of the vector I_A. By drawing a series of such points the locus of I_A can be drawn, and I_B which makes the constant

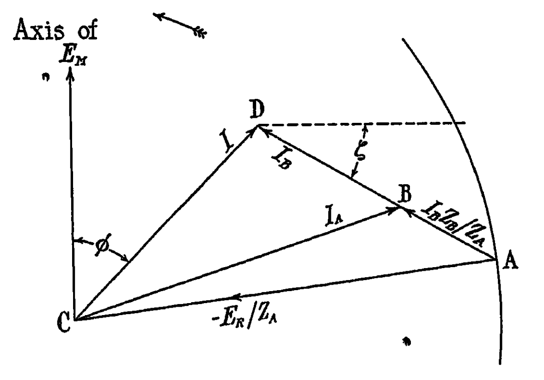

FIG. 10.

angle ζ with the horizontal can be filled in where desired.

It is seen that the relation of ζ, the natural angle of lag of the feeder, to ϕ has an important bearing on the shape of the diagram, and a critical case occurs when $\zeta = \phi$, the angle between I and I_B being in this case 90°.

The first example is taken under these conditions and is drawn for $\phi = \zeta = 36° 52'$, that is to say,

cos $\phi = 0{\cdot}8$ and $x/r = 0{\cdot}75$. The simplest relation between the feeder impedances is also taken in this example, namely $Z_B = Z_A$.

Fig. 11 is drawn for this case and shows the locus of I_A. It will be seen from the diagram that at no load (where $I = 0$) both I_A and I_B equal $\frac{1}{2}I_L$. In other words, at no load, due to the phase shift introduced by

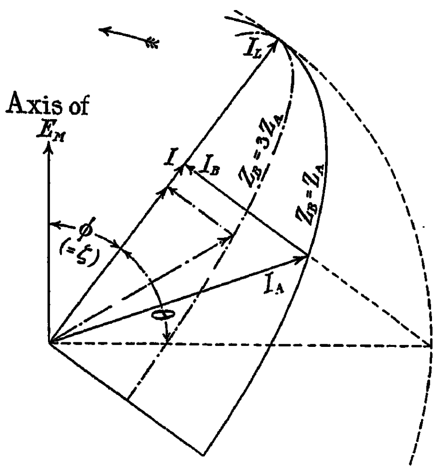

FIG. 11.

the regulator, there is a circulating current in the feeders equal to half the full-load current. It is for this reason that single polyphase regulators are not recommended for use in ring-main systems.

The values of the currents I_A and I_B for varying values of I (in terms of I_L) are plotted in Fig. 15, whilst

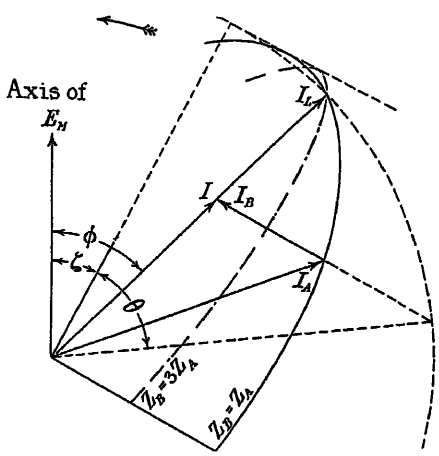

FIG. 12.

the values of total copper losses $(I_A^2 + I_B^2)$ are plotted in terms of I_L^2 against varying values of I in Fig. 16. If Z_B is greater than Z_A the circulating current is reduced, and the chain-dotted curve in Fig. 11 is drawn for $Z_B = 3Z_A$, the ratio of x/r and the other conditions remaining as before. In this case the no-load circulating current is only one-quarter of the full-load current.

Fig. 12 is drawn for a single regulator when ζ is not equal to ϕ. Here cos ϕ is taken as $0{\cdot}70$ ($\phi = 45° \, 34\frac{1}{2}'$) and $\zeta = 30°$. The full curve represents the current locus when $Z_B = Z_A$, and the chain-dotted curve represents the locus when $Z_B = 3Z_A$. The currents and losses corresponding to the full lines ($Z_B = Z_A$) are plotted in Figs. 15 and 16 respectively alongside those of the previous case.

Fig. 12 shows that at full load, θ, the angle through which the axis of the regulator is turned from its "maximum boost" position as understood in the previous sections of the paper, is not zero but is $(\phi - \zeta)$. The reason for this is that the regulator must be turned through such an angle that its voltage when acting on the impedance of the feeder will produce a current in phase with the load current I. This figure also shows that if the regulator be moved in the other direction the diagram is not symmetrical round I_L, and that in one position the regulator, though only producing a voltage equal to $I_L Z_A$, will keep the voltage constant when a current rather greater than I_L is flowing.

Turning now to the double regulator, the conditions are different. Instead of E_R swinging round to meet the conditions of load, its phase angle remains constant

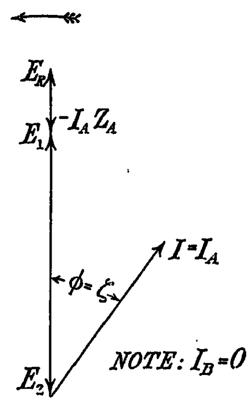

FIG. 13.

(for simplicity assumed in phase with E_M), and only its magnitude varies.

In the critical case where $\zeta = \phi$, the whole diagram collapses into a line as shown in Fig. 13, and I_B is zero throughout. There is no circulating current, and no loss introduced due to it.

Where ζ is not equal to ϕ, however, the regulator E.M.F. is not in exact phase with the impedance drop caused if I flowed entirely through feeder A, and consequently a small circulating current is always present.

A construction very similar to that of Fig. 10 can be used and is shown in Fig. 14, using the same constants as in Fig. 12. In this case an axis CA is drawn making an angle of ζ with the vertical axis. A perpendicular DA is dropped on this axis from D, where CD represents the total current I_L.

DA is cut in B in the proportion

$$DB/BA = Z_A/Z_B$$

Then $I_A = CB$.

If the figure is drawn for full load, then for any other load the triangle is similar and CB is itself the locus of the vector I_A. Consequently for any given case, I_A and I_B bear a constant relation to I.

Since CA represents E_R/Z_A it follows that

$$\frac{E_R}{Z_A} : I = \mathrm{CA} : \mathrm{CD}$$

or

$$E_R = \frac{\mathrm{CA}}{\mathrm{CD}} I Z_A$$

In other words, the value of E_R required is slightly less than IZ_A, since the current passing along feeder B has

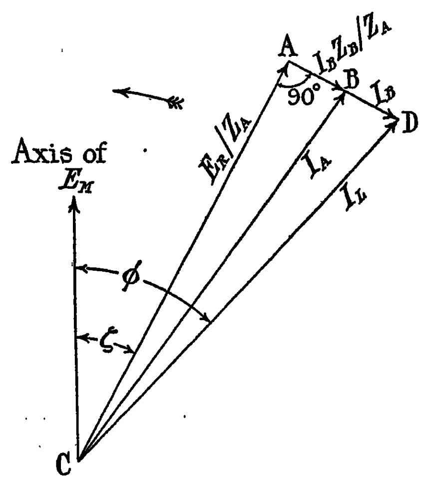

FIG. 14.

a small component in phase with I. Fig. 15 shows how the current divides into I_A and I_B in the four foregoing cases, while Fig. 16 shows the comparative losses where unity is taken to be the loss occurring when I_L flows along feeder A with feeder B open-circuited, the losses in the regulator itself being neglected.

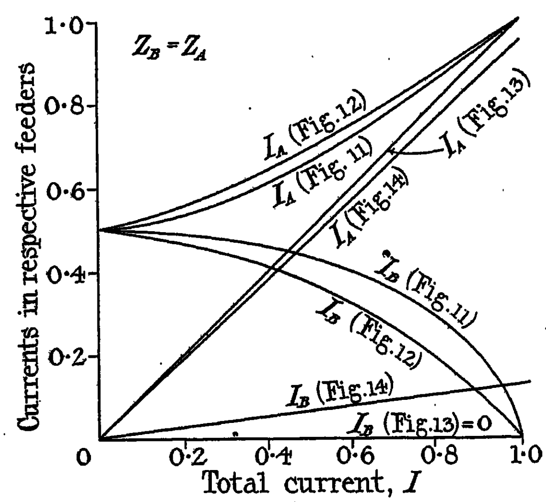

FIG. 15.

As single-phase regulators have, in common with the double regulator, no phase-shift apart from that due to their own impedance, they give the same curves as the double regulator. It is seen that except in the critical case where ζ (the natural angle of lag of the feeder) equals ϕ (the angle of lag at which current is to be transmitted), the double regulator does not give perfect results. Since usually, however, ζ is of the same order as ϕ, this slight lack of perfection is not of very great importance.

To attempt to adjust the angle of boost of the double regulator so as to ensure that ζ follows ϕ (which might be done by turning the two rotors independently, or by the use of a differential, or by the rotation of the stators in addition to the rotors) appears to be an additional complication that is not worth considering, particularly as in practice ϕ does not usually remain constant, and a considerable number of instruments would be necessary to inform the operator as to the exact conditions in the circuit and the exact steps to take to adjust the phase angle as well as the magnitude of the boost from time to time.

REGULATOR IMPEDANCE.

The effect of regulator impedance on the secondary E.M.F. is two-fold. First it causes a variation in the

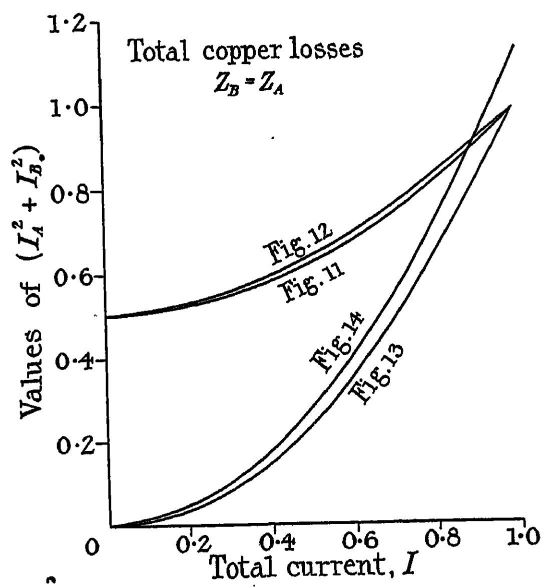

FIG. 16.

terminal secondary E.M.F., and secondly it causes a variation in the phase angle of the secondary E.M.F.

This can be more easily understood by reference to Fig. 17, where

E_1 = primary E.M.F.,
E_R' = secondary E.M.F. referred to the primary,
I_{PM} = primary current,
I_M = magnetizing current,
I_2' = secondary current referred to the primary,
r_1, x_1, Z_1 = resistance, reactance, and impedance of the primary, and
r_2', x_2', Z_2' = resistance, reactance, and impedance respectively of the secondary referred to the primary.

As the phase and magnitude of I_2' vary, so the position and magnitude of E_R vary, and if the current in the secondary winding of the regulator be leading with respect

to the voltage generated in it [see Fig. 4 (*a*)] it is possible for E'_R to be greater than E_1. It is also possible for E'_R to lead E_1.

In general, however, at full load, with lagging currents E'_R will be less than E_1, and this drop must be allowed for in the design of the regulator. The open-circuit voltage is therefore larger than the rated voltage of the machine. Further, since the numbers of both the primary and secondary conductors must be whole numbers, the exact ratio may be difficult to obtain in the design office, with the result that a little extra margin is provided in the regulator.

The term "over ratio" is generally used to represent the excess of the actual no-load secondary voltage over the rated secondary voltage. This variation in the magnitude of the secondary E.M.F. with load causes a slight inaccuracy in the preceding geometrical diagrams, but the effect is only small. The small phase difference between E'_R and E_1 also causes a slight inaccuracy in

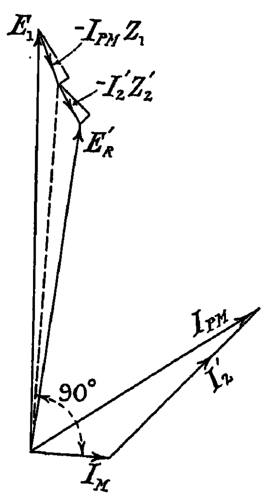

Fig. 17.

these diagrams, since with the single regulator the phase difference between the secondary and primary E.M.F.'s is not exactly equal to θ, but is only approximately so. In practice the only effect of these two inaccuracies is that usually the rotor has to be moved mechanically by a degree or two more than would correspond to the angle θ in the various diagrams.

In the double regulator the lags introduced by impedance in the two halves do not cancel out, and consequently the secondary E.M.F. is not quite in the same straight line as the supply E.M.F., and this is also the case with the single-phase regulator. The effect of this in a divided circuit is to cause an apparent slight increase in the angle ζ. In practice, however, the effect of these slight inaccuracies in the geometrical theory may usually be neglected.

The losses in a regulator are important since they reduce the overall efficiency of transmission, and particularly since the iron losses of the regulator must be supplied during the whole time that the regulator is in circuit.

The full-load losses of a regulator (including the so-called "load losses") vary from about 4 per cent of the kVA in a large regulator to about 8 per cent in a small one. On a 0·8 power factor circuit at full load these figures correspond, with a regulator giving a boost of ± 10 per cent, to losses of one-half of 1 per cent and 1 per cent respectively of the total power transmitted.

Operation and Control of Induction Feeder Regulators.

In all but the smallest sizes, feeder regulators are made of the oil-immersed type, usually self-cooled, but occasionally in the largest ones the oil is water-cooled.

The tanks are of standard transformer tank design and either circular or rectangular in plan.

The regulator is usually arranged with its axis vertical, the operating gear being mounted on top. This operating gear consists of some form of reduction gear, either single worm, double worm, or single worm and spur gear, driven either by a handwheel or by motor.

One worm at least is usually made of the non-reversing pattern, but in the majority of cases a brake is also fitted. This not only assists in stopping the operating motor, but also helps to prevent the regulator from creeping back due to vibration or any other cause. Small regulators are frequently fitted with a permanent brake, the extra power required to operate the regulator with the brake still on being exceedingly small.

Small regulators may be hand-operated where they can be conveniently located alongside the switchboard. The majority of regulators are, however, motor-operated. In this case limit switches are provided to prevent the motor from turning the rotor far enough to bind on the safety stops. The brake in this case is usually electrically operated, releasing when current is switched on to the motor, just as in the case of a crane.

The operating motor requires a low-tension supply (usually alternating current), a squirrel-cage motor being used, although a d.c. operating motor may be employed where convenient. In either case the motor is usually switched straight on the line.

For hand control, the switchgear controlling the operating motor is operated by hand or by means of push-buttons. For automatic working the motor circuit is closed by a contactor controlled by a voltage-regulating relay, two contactors being provided, one for each direction of rotation of the operating motor.

Where an automatically operated regulator is installed at the supply end of a feeder, a "line compensator" is required in order to keep the pressure constant at the far end. This line compensator consists of a resistance and reactance set (by trial if necessary) to correspond to the line resistance and reactance. It is fed through a pair of current transformers and is arranged to reproduce in miniature the drop in the line, both in relative magnitude and phase angle. It is inserted in the circuit of the voltage-regulating relay, which thus responds to the voltage at the far end of the line.

The full diagram of connections for such an automatically controlled motor-operated regulator is shown in Fig. 18. The voltage-regulating relay can be set so as to ensure that the voltage at the end of the feeder shall

not vary by more than 1 per cent from its mean value. In practice it is frequently found advisable to increase this allowance to $1\frac{1}{2}$ or even 2 per cent in order to prevent the regulator from hunting in case of slight variations of supply voltage or heavy fluctuation of load.

The time taken for the regulator to operate, following a change in the voltage, is very small and depends on the gearing, which is usually designed to operate the regulator rather more slowly in the case of the larger regulators. Average figures obtained from several makers indicate that a ± 10 per cent regulator will move over from full negative to full positive boost in from 20 to 40 seconds.

The time of starting up is negligible. Oscillograph tests on a recent 346 kVA automatic regulator show that the operating motor reached full speed within 1/5th sec. of the operation of the voltage-regulating relay, while a similar period covered the stopping of the motor after the voltage relay had opened.

Apart from the control gear, an induction feeder regulator is usually installed without any switchgear at all. It is permanently connected in the feeder circuit and is alive whenever the feeder is alive. Should it be essential that switchgear be provided to isolate the regulator without breaking the feeder circuit, this can be conveniently arranged by a series of oil switches.

The double regulator, if turned to the "no boost" position, may safely be short-circuited on the secondary side prior to cutting out.

With the single regulator this is not the case, and it is necessary to short-circuit the secondary winding through a suitable reactance, isolate the regulator, and then short-circuit the reactance. On account of the reliability of the induction regulator, however, it is not usual to install any such isolating switchgear.

The cost per kVA of an induction regulator varies over wide limits depending on output, voltage and periodicity. Relatively large three-phase regulators for 50 periods may, however, be purchased * for from £3 to £4 per regulator kVA, this figure including all automatic devices. On a ± 10 per cent regulator this corresponds to from £0·3 to £0·4 per kVA supplied.

The principal field for the induction feeder regulator is in interconnector circuits, where the boost is required to be gradual and capable of very fine adjustment, and in supply feeder circuits where boosts greater than 5 per cent are required. Below this figure the single-step boosting transformer, giving a boost of from 3 to 4 per cent, besides being cheaper, will usually do all that is required without too great a complexity of switchgear. Above this figure the multi-step boosting transformer is a possible rival, but on account of the complication and expense of the switchgear, and tappings necessary to allow of the boost to be altered without breaking the feeder circuit, its installation is not looked upon with much favour either in this country or in the United States.

* At the date when the paper was written.

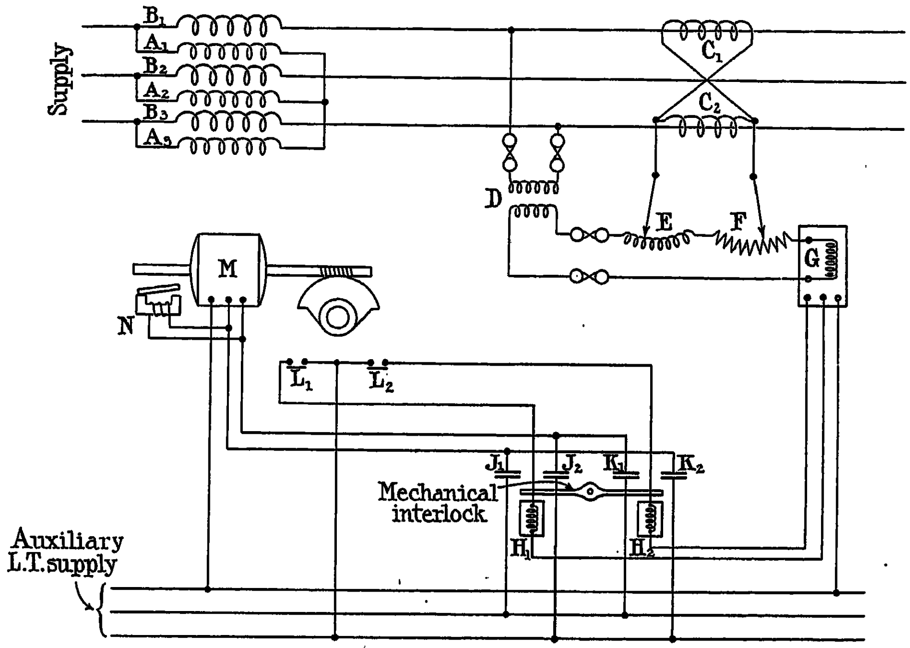

FIG. 18.—Diagram of connections of automatically controlled induction regulator.

A_1,A_2,A_3 = primary windings of induction regulator.
B_1,B_2,B_3 = secondary windings of induction regulator.
C_1,C_2 = current transformers.
D = potential transformer.
E = reactance leg of line compensator (adjustable).
F = resistance leg of line compensator (adjustable).
G = voltage-regulating relay.

K_1,K_2 = double-pole contactor.
L_1,L_2 = limit switches (normally closed).
M = operating motor.
N = brake.

Discussion before the North-Eastern Centre, at Newcastle, 26 January, 1925.

Mr. W. G. Bass: The author has succeeded in making a very useful contribution to the subject of induction voltage-regulators. He has, however, set out to describe the uses and possibilities of induction regulators as applied to feeder and interconnector circuits, and in this I do not think he has been so successful. The general subject of feeder voltage-regulation covers so wide a ground that a comprehensive treatment of it cannot be made within the limits of a paper which confines itself principally to the description of one type only of feeder voltage-regulator. On page 868 the author states that "the induction regulator, though expensive, is the only practical device which permits the control to be gradual" and in the last paragraph of the paper he says, "the principal field for the induction feeder regulator is in interconnector circuits, where the boost is required to be gradual and capable of very fine adjustment, and in supply feeder circuits where boosts greater than 5 per cent are required." At one time apparently the gradual control was deemed to be a most desirable property of a feeder voltage-regulator. In an endeavour to approximate to it step-switch regulators were designed many years ago to give a boost of 10 per cent in no less than 14 steps. Actually, in operation it has been found that steps of less than 3 per cent are not necessary to secure an effective control of the current transmitted in parallel feeders. Also, gradual control is not necessary in the case of regulators for use in low-pressure circuits. Rapid variations of 2 per cent in the voltage are not detected by the eye and do not give cause for complaints by consumers, therefore a step-switch regulator which boosts the voltage in steps of 2 per cent can safely be used. The gradual-control feature of the induction regulator therefore not being of great practical use, there is no point in buying an expensive type of regulator which provides it. This means that the other types of regulator are in competition with the induction type, and in the matter of price the latter is invariably at a disadvantage, particularly in those cases where phase-shift is objectionable and the double polyphase type has to be used. I have in mind one job an induction regulator for which was quoted at a price 200 per cent higher than that quoted for a contactor-type regulator to do the same duty. The reduction in the number of steps has the effect of considerably cheapening the step-switch regulator. Further, switchgear difficulties are considerably reduced in the modern arrangement of this regulator, the switchgear being connected in a comparatively low-voltage circuit. The system permits of the use of standard switchgear over a wide range of booster kVA and voltage, and effects a further saving in cost. On this account the step-switch regulator is used to a very considerable extent in feeders which require a boost considerably greater than 5 per cent. As an example of this the Newcastle Electric Supply Co. are now installing in an 11-kV feeder a step-switch regulator which will give a boost of 36 per cent. Where the operation of the regulator is frequent the step-switch type suffers, but in this case the contactor type is the cheaper alternative and one which promises to be altogether more satisfactory. It employs standard contactor gear which is of very robust construction and capable of thousands of operations before the contacts have to be renewed. A further point bearing on the question of cost is not discussed by the author. It is a difficult matter to insulate conductors in slots for a voltage greater than 13 kV and it is therefore necessary in e.h.t. feeders to use step-down and boosting transformers for the shunt and series windings respectively of the induction regulator. In this case the difference in cost between the two types of regulator is therefore the difference between the induction regulator in the one case and the switchgear in the other. If the range of boost is not excessive the switchgear will prove to be the cheaper, particularly if phase-shift has to be avoided and the double regulator used. Where a wide range of boost is required it may be economical to use an induction regulator in conjunction with a step-switch type, the number of steps on the latter being reduced to a minimum and the induction regulator boosting between the steps. On account of the smaller range of boost required of the induction regulator in this case it is possible that the phase-shift introduced by a single regulator would not be sufficiently great to prove objectionable and, therefore, the double regulator would not be necessary. I should be glad to know whether the author has considered this combination of the two types for feeder voltage-regulators. Another point bearing on this question of cost is the characteristic of the induction regulator that it gives a negative as well as a positive boost and as much of the one as of the other. When the regulator is used in conjunction with a transformer it may be possible so to fix the voltage ratio of the latter that the negative boost of the induction regulator can be used. When used as a feeder voltage-regulator, however, the negative boost is useless, so that the purchaser is paying for twice the booster kVA required. I have wondered whether it would be possible to avoid this by connecting in series with the shunt winding a series winding which would have the effect of giving a permanent boost of one half the total. The remaining half, which would be variable, would be so applied as either to boost up or buck against this permanent boost. What is the author's opinion of this proposal? One point which is not touched upon in the paper is the capability of the induction regulator to withstand the stresses resulting from the passage through it of the short-circuit current of the feeder in which the regulator is installed.. This may be, depending upon the circuit impedance, more than 20 times the normal full-load current, and it is most essential that a feeder voltage-regulator be capable of withstanding the resulting stresses. It is possible to provide for this condition in the case of the step-switch regulator, and I shall be glad to have the author's assurance that it is also possible in the case of the induction voltage-regulator. The author does not refer to the three-wire regulator. In networks which have been changed over from direct current to single-phase three-wire alternating current it is possible that such regulators

will be of use. They are cheaper than the alternative two single-phase regulators, one installed on each side of the neutral, and it would have been of interest if the author had described them together with their characteristics. Their use is limited, I believe, to circuits in which the out-of-balance is not excessive, say less than 10 per cent, and I should be glad if the author would confirm this. The automatic operation of single-phase regulators leads to difficulties. In the section dealing with automatic operation the author assumes a convenient auxiliary low-tension supply and the use of a squirrel-cage motor. It should, however, be assumed that no independent source of supply to the motor can be provided. This is a quite reasonable assumption to make as it may not be possible to provide it under any circumstances whatsoever, and if possible it may be altogether too costly. Therefore, with the regulator for use in a single-phase three-wire circuit a single-phase motor must be provided. The induction type has not proved suitable, so far as my experience goes. The most suitable characteristics for this motor are those of the commutator type. In addition it must be capable of very frequent starting up. A satisfactory motor having these properties is difficult to obtain and I should particularly like to hear what the author has to say with reference to such motors, which form a most important link in the equipment of the single-phase automatic feeder voltage-regulator.

Mr. A. W. Crompton: I agree with the author that with the increase in the number of a.c. lighting networks and also in the schemes of interconnection, etc., the need for regulators is greatly extending. Unfortunately, neither the step type nor the induction type has reached that stage of development which meets all requirements. The comparative cost of the induction type as against the step type is decidedly in favour of the latter. The largest induction-type regulator referred to (1 750 kVA) is not large enough to deal with the permissible loading of some main transmission lines. Incidentally there appears to be a certain amount of laxity amongst operating engineers when referring to the rating of regulators, the correct figure being of course that based upon the maximum voltage boost and not upon the line voltage. The boost given for a certain relative position of the stator and rotor appears to depend upon the power factor of the load supplied. The same simplicity of operation does not therefore obtain as with the step type, in which the steps can be numbered to correspond to definite voltages. The chief advantage of the induction regulator in providing a means of varying the voltage very gradually would appear to be of great utility in many ring-main systems, enabling full use to be made of the copper. For example, in the case of a ring main where one side of the ring may be fully loaded due to load near the power station, the other side may only carry a comparatively small load due to the distance away of the first substation. Reference is made to the reliability of the induction regulator, but unfortunately this does not apply to the automatic control gear, and it would certainly appear advisable to provide means of isolating the regulator so that during or after the repair of any essential part of the gear the regulator may be operated clear of the circuit in which it is normally used.

Mr. R. J. H. Beaty: The fitting of tappings to the main transformer is a makeshift that can be tolerated where the power is small and the pressure moderate, but engineering instinct and experience tells one that it would be bad practice when dealing with a large power at extra high pressure. In such a case a simple boosting transformer should be connected in series with the feeder and have its primary fed from either an induction regulator or a transformer with tapping switch. With this arrangement, if a short-circuit occurs on the regulating device the boost will simply be lost, but the feeder need not be cut off; whereas with tappings on the main transformer, if a short-circuit occurs on the tapping switch or its connections the load will be lost and possibly the transformer as well. The series transformer could be insulated so that the risk of a breakdown to earth would be extremely small, and a short-circuit would not be a serious matter. It is true that the primary of the regulator would have to be cleared, but as this represents only a fraction of the feeder load, and as the regulator has considerable impedance, the momentary disturbance to the system would be small. The author gives the full-load losses as 4 per cent in a large, and 8 per cent in a small, induction regulator. The corresponding figures for a tap-switch booster would be 1½ per cent and 3 per cent, but it must be admitted that the latter device will not do all that an induction regulator will do. For a motor-driven boosting alternator one would expect these losses to be 12 per cent and 24 per cent. Many members will have seen d.c. power stations equipped with small motor-driven feeder boosters in which the losses are more than 30 per cent.

Mr. C. Turnbull: In our own area we have a bulk supply through long feeders, and there is a tendency for the pressure to fall during the times of heavy load, and for it to rise excessively on light load. We have recently installed a booster and are able to give consumers a good pressure on the peak loads and to reduce the pressure in the middle of the night, which greatly improves the life of street lamps, and also reduces the number of lamp failures. In ordering a booster, the natural tendency is to arrange it to boost upwards, but in some circumstances it may be found better to set the pressure high by means of the transformer tappings, and to boost downwards at times of light load. This will give the booster less work to do. In many cases a good arrangement is to arrange the transformer tappings so that the booster has a minimum of work to do, only boosting up when the load is heavy, and boosting down when the load is light, but in times of normal load doing little or no work.

Mr. L. H. A. Carr (*in reply*): The practice in this country with regard to boosting transformers and induction regulators has not yet become crystallized, since the need for such forms of apparatus is only in its infancy. This need is, however, growing, and it was largely to explore the position from the point of view of the induction regulator that this paper was written, rather than to lay down a hard and fast rule of "standard practice." At the same time, one cannot at all agree with most of Mr. Bass's contentions. Where steps of 5 per cent in voltage are sufficiently fine, the

boosting transformer is probably—one might almost say certainly—the better alternative; but it has yet to be proved, first, that steps as coarse as this can be used in the majority of cases, and secondly that where smaller steppings are necessary (taking into consideration first cost, reliability, and cost of maintenance) the boosting transformer is the better scheme. Further, I cannot agree with Mr. Bass (and neither apparently does Mr. Crompton) that the gradual-control feature of the induction regulator is "not of great practical importance."

With very small installations the relative figures of cost quoted by Mr. Bass are probably correct, but the larger the output required, the cheaper becomes the induction regulator compared with the transformer-step-switch combination. Further, as the permissible stepping limit becomes smaller, so the cost and complication of the boosting transformer combination increases, as must also its liability to breakdown, while the necessity for continuity of supply during switching operations still further increases the cost of this system. It is therefore found in some of the larger projected installations that the induction regulator costs little more than the transformer scheme, while having the advantage of possessing fewer links in the chain and hence less liability to break down.

Mr. Crompton suggests that the reliability of the automatic control gear may not be so high as that of the regulator itself, and that a breakdown may occur due to this. None of the power, however, goes through the control gear, and as hand operation is always provided as a stand-by, the breakdown of the control gear does not necessitate putting the regulator out of action.

Mr. Bass suggests the use of a step-switch transformer together with a small induction regulator to bridge the gaps. This is quite feasible, but except in a large installation the first cost of such a scheme would be relatively high, as it must be remembered that the cost per kilovolt-ampere of a regulator falls rapidly as the size is increased, so that, conversely, if the size of the regulator is decreased the cost per kilovolt-ampere (of the regulator) increases rapidly, and little saving is made in the cost of the regulator if the latter falls below a certain critical size for each voltage. For large installations, however, the scheme is worth consideration, which as a matter of fact it has received in certain specific cases.

With regard to the cancellation of the negative boost, it would be possible to place half the secondary winding on the primary member, and so produce a boost varying from zero in one direction only. While I believe this has occasionally been done in the case of a single-phase induction regulator used for testing purposes, the construction is of no advantage in the feeder regulator and there is no saving obtained by adopting it. The losses would remain the same, and the only result (besides an infinitesimal lowering of the leakage reactance) would be the production of a regulator to give from 0 to, say, + 10 per cent boost, instead of − 10 per cent to + 10 per cent, at the same cost and with the same losses. In a large installation, where a smaller regulator could be built economically, instead of the above scheme it would be wiser to consider a + 5 per cent boosting transformer permanently in circuit, together with a ±5 per cent regulator. The alleged uselessness of the negative boost has, however, been over-stressed in the discussion. The question does not arise in the case of complete new installations where the transformers can be made of a suitable ratio, and even when the regulator is added to an existing transformer distribution system the transformer voltage may frequently be adjusted, since the majority of large transformers appear to be provided with taps covering from − 5 per cent to + 5 per cent. Further, in an interconnector between two power stations both positive and negative boost are required, so that the boost may be set to correspond with the power flow.

I can assure Mr. Bass that induction regulators for feeders are most certainly designed to withstand the very large stresses that may occur on short-circuit, special attention being paid to the bracing of the end windings, strength of gears, etc.

I regret that I have no particulars available of single-phase three-wire regulators. Such a regulator is, however, perfectly feasible, and would have two secondary windings on the same core, a single primary winding being connected across the outers. So long as the out-of-balance current is small, this arrangement would work quite satisfactorily. The advantage of this scheme is that it would be cheaper, and slightly more efficient than two single-phase regulators each of half the capacity. For operating a single-phase regulator, in order to overcome the difficulty of the limited starting torque of the single-phase induction motor, at least three alternative schemes may be employed:—

(1) The motor is allowed to run continuously, clutches or ratchets being operated automatically when a change of boost is required.

(2) The motor is geared down to the regulator through a low-speed crank and connecting rod operating a ratchet device. The gear is so devised that the motor always starts with the pawls of the ratchet out of engagement, and thus starts light.

(3) The motor drives the regulator through a centrifugal slipping clutch.

In reply to Mr. Crompton, the boost given for a certain relative position of stator and rotor depends, for all practical purposes, solely on that position. The only effect of the power factor of the load is to change the vector relationship of the internal impedance drop of the regulator, the effect of which change is practically imperceptible at the terminals. It is, therefore, possible to mark the regulator so that definite settings correspond to certain definite amounts of boost. Finally, I would state that the kVA figures quoted refer to the output of the regulator and not to the capacity of the feeder to which it is connected.

POLYPHASE TRANSFORMER MAGNETIZING-CURRENT WAVE-FORMS.*

By P. KEMP, M.Sc.Tech., Member, and H. P. YOUNG, Associate Member.

(*Paper first received 27th January, and in final form 22nd April, 1925.*)

SUMMARY.

The paper deals with the analyses of the magnetizing currents taken by groups of transformers connected in various manners for operating on polyphase (and particularly on three-phase) systems. The method of treatment employed is to assume that a sine wave of flux necessitates the application of a peaked wave of magnetizing current, and that the difference between this desired wave and the wave actually obtained brings about various modifications in the behaviour of the apparatus. The properties of the star, delta, tee- and vee-connected windings are discussed, particularly with reference to harmonics, oscillographic confirmation being given where possible. Various six-phase systems are also discussed, in view of their importance in connection with rotary-converter work.

For convenience, a number of oscillograms have been omitted, only the results being quoted in the paper itself.

It is a well-known fact that third-harmonic currents cannot flow in a balanced three-phase star-connected system with isolated neutrals, and that a three-phase delta constitutes a short-circuit path for such currents. Furthermore, the magnetizing current flowing through a winding surrounding an iron core contains a very considerable third harmonic if the iron is saturated, assuming the applied E.M.F. to be sinusoidal in wave-form. If, therefore, three such magnetizing windings be connected in star and a sinusoidal E.M.F. be applied to the combination, the flux densities in the cores being sufficient to cause saturation, it follows that since the third-harmonic currents cannot flow directly, the form of the M.M.F. and the resulting flux waves must be modified in some way.

The object of the present investigation is to examine certain aspects of this subject and to trace out the mechanism whereby the various results are obtained. For this purpose a method of treatment will be employed which involves the idea of considering a sine wave as being composed of a peaked component consisting of a sine wave and a third harmonic, together with a third-harmonic sine component equal and opposite to the third-harmonic part of the main peaked component. This idea is illustrated in Fig. 1, which shows a resultant sine curve A, and its two equivalent components, B and C, these being the peaked and third-harmonic components respectively. As ordinary transformer magnetizing currents can be represented to a fair degree of accuracy by a sine wave together with a third harmonic, and very accurately by a sine wave together with a third and fifth harmonic, the applied E.M.F. being sinusoidal, the main peaked component, B, can be made to represent the main fundamental magnetizing current, whilst the third-harmonic component, C, will be employed in producing a third-harmonic flux. The treatment could be carried further, if desired, by considering the third harmonic itself as being peaked, the difference between the peaked and the sinusoidal third harmonic giving rise to a further magnetizing current of nine times the fundamental frequency.

In the case of a balanced three-phase star-connected choking coil supplied with a sinusoidal line voltage, the neutral points being isolated, third-harmonic currents cannot circulate. Since, however, a sinusoidal phase voltage demands a magnetizing current containing a third harmonic, it follows that the phase voltage is not sinusoidal. The difference between the actual phase-voltage wave-form and the sine phase-voltage wave-

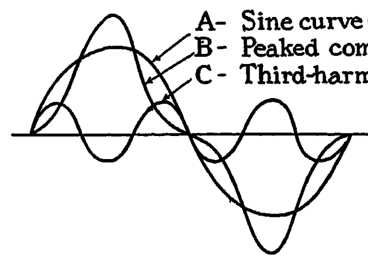

FIG. 1.—Composition of sine curve.

form, obtained from a consideration of the line voltage, must be exactly neutralized by a corresponding difference in the other phase. This difference consists of a third-harmonic voltage; for since the fundamental E.M.F.'s directed away from the neutral point are 120° out of phase, the third-harmonic voltages are 360° out of phase and so cancel out between lines. (Higher harmonics such as the ninth, etc., are here neglected.)

If the line potentials are symmetrical with respect to earth, the potential of the neutral star-point will not be that of earth, but will oscillate about earth potential at third-harmonic frequency with a magnitude equal to that of the third-harmonic phase voltage. If the choking coil neutral point is in electrical connection with the supply neutral point, these third-harmonic voltages will be expended in forcing third-harmonic currents through the system, the fourth wire acting as a drain since it forms the return path of all three third-harmonic currents. The relative magnitudes of the impedance of the fourth wire and the phase windings will now determine the proportion of the third-harmonic voltages which is absorbed in the windings themselves. The

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the papers to which they relate.

oscillation of the neutral potential is reduced and, if the return path constitutes a short-circuit, the neutral potential is practically stabilized at earth potential, the oscillation being damped out.

In the case of the delta-connected choking coil, a sinusoidal line voltage will bring about phase currents which contain a third harmonic. The fundamental components of these currents will flow in the line conductors, but the third-harmonic components will all be in phase with each other, and so will circulate around the delta, which constitutes a short-circuit to them. The third-harmonic currents thus do not appear in the lines, and the third-harmonic voltages are suppressed.

It is interesting to consider the mechanism whereby a generator giving a pure sine wave of voltage, not only between lines but also between each line and the star point, can supply the primary phases of a three-phase choking coil or a transformer with the necessary third-harmonic magnetizing current of whatever amplitude may be demanded. The condition will be simply but adequately represented by the case of a single-phase generator developing a pure sine wave of E.M.F. directly connected to a choking coil. Neglecting all losses in

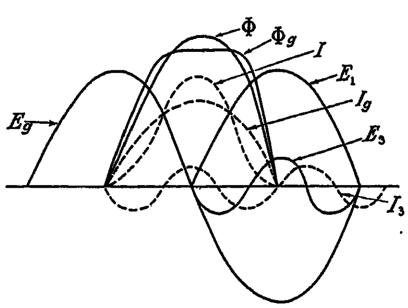

FIG. 2.—Production of third harmonic in current wave of choking coil.

the latter, the mechanism is explained by the waves shown in Fig. 2.

The generator voltage, E_g, sets up a sinusoidal magnetizing current, I_g, lagging by 90°, and this gives rise to a flat-topped flux wave, Φ_g. This in turn induces a reactive E.M.F. which can be obtained by the differentiation of the flux wave. This reactive E.M.F. will consist of a fundamental component, E_1, which is balanced by the applied generator voltage, and a third-harmonic component, E_3, which is free to circulate a third-harmonic current, I_3, through the circuit. This current, lagging by its appropriate angle behind the voltage E_3, can now be combined with I_g to give the resultant magnetizing current, I. In addition, however, it sets up a harmonic flux in phase with itself, and this, combined with the flux directly due to the applied voltage, brings about the resultant flux wave, Φ. This wave is still flat-topped to a certain extent, but not so much as is the wave represented by Φ_g.

It will be noticed that the generator only supplies directly the fundamental magnetizing current and the current necessary to account for the various losses. This is true whether the star points of the generator and choking coil are isolated or directly connected together. The choking coil supplies the harmonic currents necessary for its own magnetization, the generator windings merely forming part of the path for the circulating currents. If, owing to the method of connection, there is no path for third-harmonic currents, the flux wave will suffer a further deformation, and this will cause the choking coil to set up additional fifth harmonics, etc., which will tend to make up the deficiency as completely as it is able.

The effects of one harmonic can only be imitated exactly by a combination of an infinite number of other harmonics, all of equal amplitude to one another and to that of the harmonic whose effects are to be reproduced. This can be seen from a consideration of the expression :—

$$E_1 \sin \omega t + E_3 \sin 3\omega t + E_5 \sin 5\omega t + \ldots = 0$$

Putting $E_1 = E_3 = E_5$, etc., this resolves itself into

$$\sin \omega t + \sin 3\omega t + \sin 5\omega t + \ldots = 0$$

and hence

$$\sin 3\omega t = - \sin \omega t - \sin 5\omega t \ldots$$

As this is not a convergent series, the effect of a dozen or so of terms does not give a useful approximation to the desired harmonic.

Indeed, since the various terms all commence in phase with one another, the initial part of the wave will be widely dissimilar from that desired. The central portion, however, corresponding to the period of saturation, will approximate fairly closely because neighbouring harmonics are on alternate sides of the zero line. The maximum value of the desired harmonic wave will be faithfully reproduced if an odd number of components be chosen.

The above ideas will be expanded so as to deal with various transformer connections, the applied E.M.F.'s being assumed to be sinusoidal in all cases.

CASE 1: STAR-STAR CONNECTION.

(*a*) *Both neutrals isolated.*—Assuming a balanced system, the third-harmonic currents cannot circulate, so that as a first approximation the magnetizing current may be considered as obeying the simple sine law. To produce a sine wave of flux, however, necessitates a magnetizing current having a third harmonic, owing to the shape of the *BH* curve, the magnitude of this third harmonic depending upon the degree of saturation. The effect of hysteresis is here neglected but will be considered later. The actual sine wave of magnetizing current may be considered as consisting of a peaked component, itself consisting of a pure sine wave together with a third harmonic, and a third-harmonic component to balance the corresponding third harmonic in the main component (see Fig. 3). The peaked component of the magnetizing current will give rise to a sine wave of flux, and the third-harmonic component may be assumed to give rise to a third-harmonic flux. (This is not strictly accurate, as the harmonic M.M.F. cannot produce the same effect as it would do if the fundamental M.M.F. were absent. The degree of saturation will affect the discrepancy.) The resultant flux wave will be flat-topped or dimpled, depending upon the degree of saturation. Both component fluxes will induce

E.M.F.'s in the primary and secondary, the wave-forms being the same in the two cases. These E.M.F.'s will lag behind their respective fluxes by 90°. The resultant wave of induced E.M.F. will thus be peaked and the harmonics set up by the transformer, which are not balanced by corresponding generator harmonics, are expended in impedance drops. The phase voltage between line and star point is thus seen to contain a considerable third harmonic. The R.M.S. value of the potential of the star point will differ considerably from that of earth, assuming the three-phase system to be balanced about earth potential. The voltage between star point and earth will produce a triple-frequency effect, its magnitude depending upon the degree of saturation in the coils.

It is found, however, that with the iron used in practice the effect is not so simple as indicated above, for the fifth harmonic is by no means negligible. The manner in which the fifth harmonic is set up will next be discussed. It was stated above that a sine wave of magnetizing current could be split up into two components, one producing a flux wave of fundamental frequency and the other one of third-harmonic frequency. The addition of two waves in this manner is true for M.M.F.'s, but is only correct for fluxes throughout the straight-line portion of the *BH* curve. When saturation commences to take place, the resultant flux due to two M.M.F.'s acting simultaneously is less than the sum of the fluxes set up by them when acting independently.

In considering the effect of a third harmonic upon a sine wave of flux, it follows that the half wave of

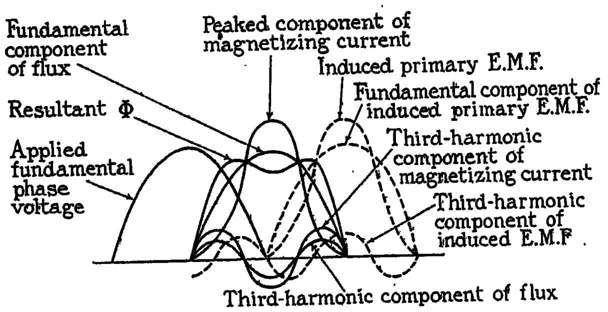

FIG. 3.—Origin of peaked phase voltage in star-connected system.

harmonic flux occurring in the middle of the fundamental half wave will have a smaller amplitude than the half waves immediately preceding and following it. This is indicated in Fig. 4 (*a*), which shows a fundamental half wave together with a third harmonic, the middle half wave of which is damped down. Fig. 4 (*b*) shows a similar effect, but in this case the distortion is due to a combination of third and fifth harmonics. The two resultants are very similar. This goes to show that owing to the gradual bending over of the *BH* curve, a fifth harmonic is introduced into the flux wave in addition to the third already described. The fundamental, third and fifth harmonics are all in phase with one another, i.e. they all commence to rise from zero in the positive direction simultaneously.

Owing to the presence of a fifth harmonic in the flux wave there will be a fifth-harmonic E.M.F. induced in each phase winding. These E.M.F.'s will not cancel out between lines as in the case of the third harmonic, but will give rise to a line resultant, causing a fifth-harmonic magnetizing current to circulate between transformer and generator, and there will be a fifth harmonic in the P.D. between transformer line terminals, even though the open-circuit induced E.M.F. in the generator be an ideal sine wave. The transformer phase-voltage can be obtained by the differentiation of the flux wave. This voltage wave, together with its components, corresponding to the flux wave shown in Fig. 4 (*b*), is represented in Fig. 4 (*c*). It will be observed that, whilst the generator supplies the fundamental magnetizing current directly, the transformer iron is

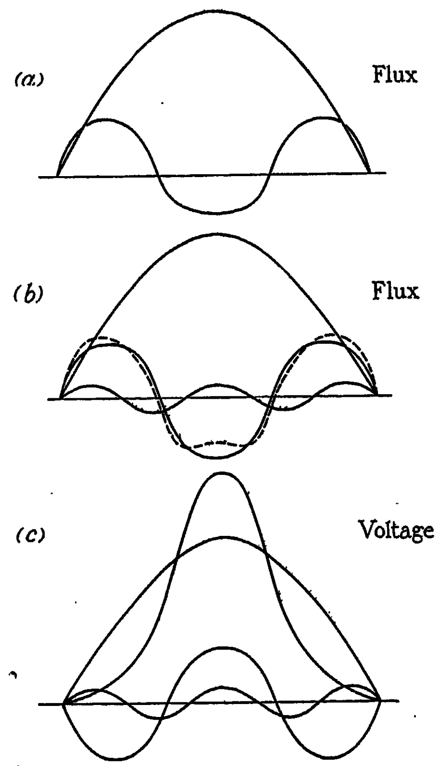

FIG. 4.—Origin of fifth harmonic.

responsible for the setting up of the voltage harmonics and hence the harmonic components of the magnetizing current. The third harmonic is absent in the magnetizing-current wave, but instead of this there is a pronounced fifth harmonic.

The phase of the fifth harmonic in the magnetizing current can be obtained from Fig. 4 (*b*). Since the fifth-harmonic flux is tending to peak the resultant flux wave, the fifth harmonic in the magnetizing current must do the same. This harmonic cannot, however, make up for the lack of third harmonic, and so the resultant flux wave is still flat-topped. The distortion of the flux wave is much less than the distortion of the corresponding voltage wave, but it can be seen quite distinctly in the oscillograms shown in Fig. 5. The flat-topped wave represents the flux wave of a group of three single-phase transformers with the neutral isolated,

the other wave representing the condition when the transformer star point was connected to the generator star point. This permitted the third-harmonic magne-

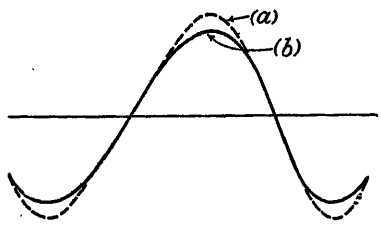

FIG. 5.—Flux waves with star points; (a) connected, (b) isolated.

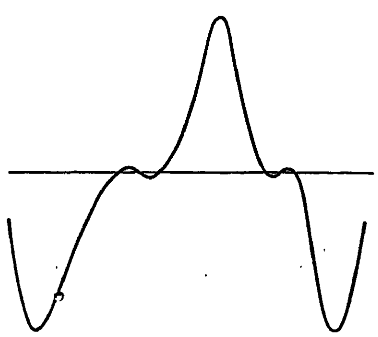
tizing current to flow and so enabled the flux wave to regain approximately its sinusoidal shape. The phase voltage of the same group of transformers when operating with an isolated neutral is given in Fig. 6. This voltage wave contains a 46 per cent third and a 10 per cent fifth harmonic, the former approximately in opposition and the latter in phase, so that they both tend to peak the resulting wave.

If a sine wave of terminal volts between lines be assumed, there may be a third harmonic in the phases (i.e. between line and neutral) but there cannot be any fifth harmonic, since if there were it would appear



$$e = 100 \sin \omega t + 46 \sin (3\omega t + 174^\circ) + 10 \sin (5\omega t + 320^\circ)$$

FIG. 6.—Phase voltage with isolated neutral.

between lines. In order to comply with this condition a very considerable fifth harmonic is set up in the primary magnetizing current, this being of sufficient magnitude to cause a pronounced dimple in the flux wave and hence in the current wave when the flux density is high. Fig. 7 shows an example of this and refers to ordinary stalloy plates in which the maximum flux density is 14 000 lines per cm². The flux wave contains an 18·4 per cent third harmonic, giving rise to an appreciable dimpling, whilst the fifth harmonic in the magnetizing current rises to the high value of 23·2 per cent. The phase voltage is thus seen to contain a third harmonic having a magnitude equal to 55·2 per cent of the fundamental voltage between line and neutral. The corresponding values for other flux densities are shown in Table 1.

The change in the phase of the fifth-harmonic magnetizing current is clearly shown in the table, and the figures seem to point to the fact that the third-harmonic phase voltage reaches an upper limit of the order of 60 per cent of the fundamental (see Fig. 8).

Considering next the effect of hysteresis, it will be assumed that a current of one frequency cannot be produced by an E.M.F. of another frequency. In the usual method of treatment this condition is not adhered to, and a hysteresis current of irregular wave-form is obtained as a result. This gives rise to a discrepancy which is commonly neglected, for if the applied E.M.F. is sinusoidal, the power factor of the hysteresis current of irregular wave-form cannot be unity, and, apart from an E.M.F. of one frequency producing a current of

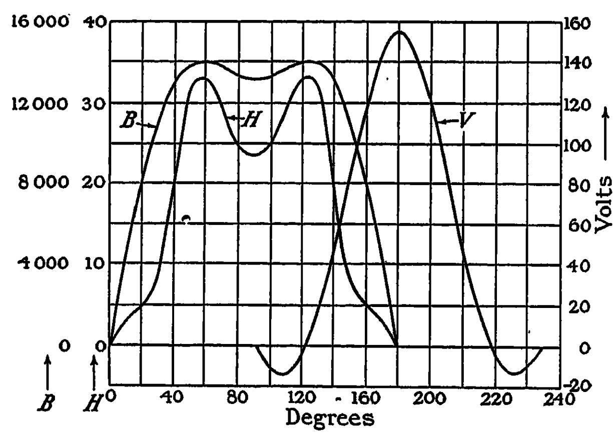


FIG. 7.—Fifth harmonic in magnetizing current with high flux densities.

another frequency, it is supposed to produce a current which cannot give rise to any watts. The current is therefore not solely a hysteresis current.

It is much simpler to assume that the applied voltage produces a sine wave of current of sufficient magnitude to account for the hysteresis loss, since this is supplied directly from the generator or other source of power.

TABLE 1.

Stalloy Plates.

Max. flux density in lines per cm²	11 000	12 000	13 000	14 000
Fundamental *H*	7·94	12·28	19·68	30·21
Fifth-harmonic *H*	+0·27	−0·56	−3·37	−7·02
Third-harmonic phase voltage	16·8 %	42·6 %	51·9 %	55·2 %
Third-harmonic flux	5·6 %	14·2 %	17·3 %	18·4 %
Fifth-harmonic magnetizing current	+3·4 %	−4·6 %	−17·1 %	−23·2 %

Subtracting this current from the total no-load current, the total magnetizing current is obtained. This now consists of a fundamental and harmonics symmetrically distributed about a 90° vertical axis, together with components more or less in phase with the voltage, tending to increase the resultant current in the first quadrant and to diminish it in the second. The result is to elevate the customary hump on the left-hand side of the wave and to depress the one on the right.

The fundamental component of this magnetizing current is supplied by the generator. This induces a flat-topped flux wave which, owing to the harmonics contained in it, sets up E.M.F.'s of various frequencies. These E.M.F.'s give rise to the various harmonics in the resultant magnetizing current and tend to eliminate the flux harmonics, reducing the distortion of the flux

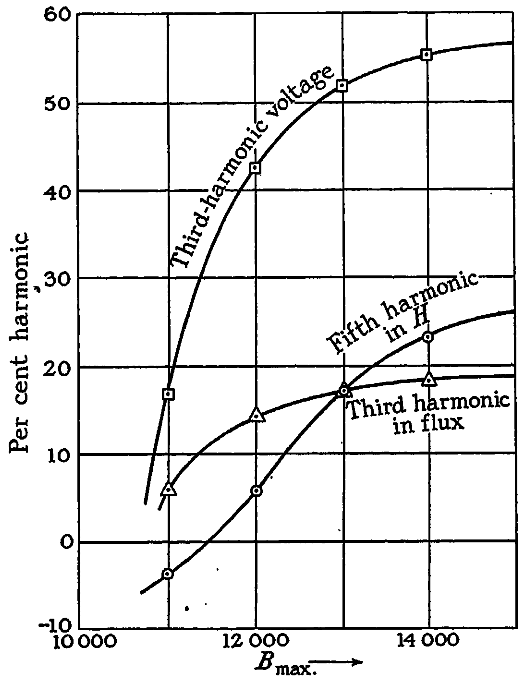

FIG. 8.—Summary of harmonics for various values of B_{max}.

wave. If no hysteresis were present, these harmonics would all be symmetrical about the 90° ordinate, but owing to the fact that the "up" magnetization curve differs from the "down" curve, some of the harmonics have a phase displacement and cause part of the familiar dissymmetry in the resultant current wave. Nevertheless, these components of the current strictly belong to the magnetizing and not to the loss portion of the current, and are derived not from the generator directly but from the transformer itself. The generator supplies only the fundamental sine wave of magnetizing current and a power component, also sinusoidal and of fundamental frequency, to account for the hysteresis loss. All harmonic currents are derived from the transformer, the shape of the flux wave so adjusting itself that these components are possible.

If the impedance of the paths of the harmonic currents were negligibly small, the number of harmonics in the current wave would be infinite and the flux wave would be approximately sine-shaped. But in the case of transformers or choking coils this condition is impossible of attainment since the reactance is directly proportional to the frequency. Again, in the case of a three-phase star-connected bank with an isolated neutral the third harmonic and multiples thereof cannot act, and the deficiency due to this cause cannot, as previously shown, be made up by the higher harmonics. As a consequence the flux wave can never be exactly sine-shaped, although a very close approximation may be obtained with favourable conditions.

In a single-phase transformer or choking coil, third-harmonic currents are possible and such currents are supplied by the transformer itself on account of its particular flux wave-forms. In the case of a balanced three-phase star-connected group with isolated neutral, these third-harmonic currents cannot flow, and hence the flux waves must adjust themselves in shape to meet the new conditions. Generally, this means flatter-topped flux waves. If the maximum flux density in the magnetic cores is the same as before, the hysteresis loss per unit volume will be the same, assuming the same frequency, and so the hysteresis current should be the same. On the usually accepted method of determining hysteresis current, this would work out differently in view of the different shape of the flux wave, and this is surely wrong. This again serves to point out that the generator supplies the sinusoidal hysteresis current, and the flux waves give rise to induced E.M.F.'s which contain harmonics and so cause the potential of the neutral to oscillate. The magnetizing currents, deficient in third harmonics, are partly obtained from the generator (fundamental) and partly from the transformer (harmonics).

(*b*) *Both neutrals isolated. Secondary delivering four-wire supply.*—It is well known that an unbalanced load to the neutral cannot be delivered satisfactorily with this combination, since the corresponding primary currents which magnetize the core, result in a serious shifting of the primary neutral point. The maintenance of the voltage on the secondary side is therefore impracticable. If, however, the primary neutral be connected to the star point of the generator windings, the unbalanced current can circulate between the primary winding and the corresponding phase of the generator winding, the phase voltages being therefore approximately balanced. These considerations apply particularly to single-phase transformers, both core and shell type, and to three-phase shell-type transformers. They only apply to a limited extent to three-phase core-type transformers, since in this case the magnetic fluxes in the three cores are interlinked, giving a very much better balance of the phase voltages.

If the secondary supplies a balanced load, however, there is a closed path for the third-harmonic components of magnetizing currents, these currents circulating through the transformer windings, lines and load impedances. As all the third-harmonic currents are in phase with one another, their arithmetical sum will return to the star point of the transformer coils via the fourth conductor.

The mechanism by which the third-harmonic magne-

tizing current is referred to the secondary may here be mentioned. Since the primary neutral is isolated, the primary magnetizing current cannot contain the necessary third harmonic and so can be represented by a peaked wave producing a sine wave of flux, together with a third-harmonic component in phase, this producing a third-harmonic component of flux. The question of saturation in the case of the harmonic is here neglected. The two component current waves form a resultant sine wave, and the two component flux waves form a resultant flat-topped flux wave. Actually the resultant magnetizing current will contain also a considerable fifth

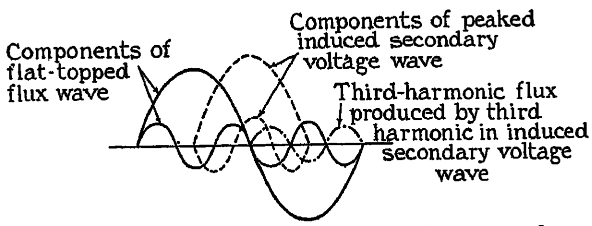

FIG. 9.—Harmonic magnetization of core from secondary.

harmonic, but that is not material to the present argument. The component flux waves may each be regarded as giving rise to independent reactive E.M.F.'s in the primary windings and to induced E.M.F.'s in the secondary windings. The sine components of the latter will circulate the load currents, the vector sum of which equates to zero, so that they do not appear in the fourth wire. The third-harmonic components of the E.M.F.'s will circulate third-harmonic currents which, being in phase, will return to the transformer secondary neutral point by way of the fourth wire. The current in this

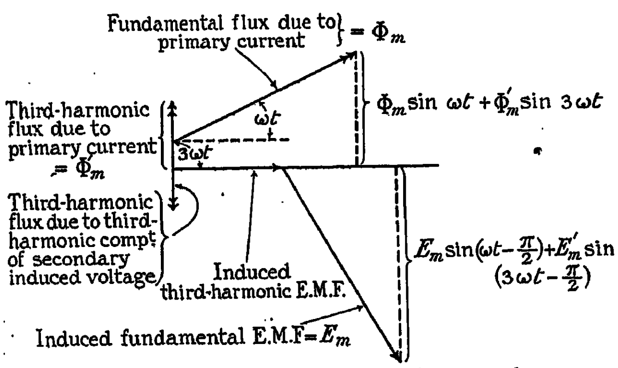

FIG. 10.—Vector diagram illustrating secondary magnetization.

wire will be the arithmetical sum of the three third harmonics. The latter will, neglecting losses, provide secondary ampere-turns which can magnetize the core, and the resulting third-harmonic flux will lag by 90° behind the voltage producing it. A reference to Fig. 9 shows that this flux tends to neutralize the third-harmonic component of flux set up by the primary ampere-turns. The hypothetical third-harmonic flux set up by the third harmonic in the induced secondary voltage wave nearly neutralizes the hypothetical third-harmonic flux produced by the primary ampere-turns. In consequence, the flux set up by the primary magnetizing current will be much more nearly sinusoidal than before, and the induced E.M.F.'s will also be approximately sinusoidal. The peak of the phase voltages will be reduced and the

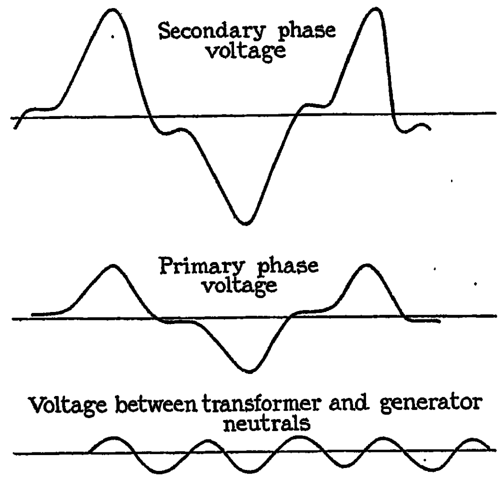

FIG. 11.—Oscillograms of star-star-connected transformers with isolated neutrals, delivering balanced 4-wire load (0·4 A).

oscillation of the primary neutral point will be largely damped down.

An alternative method of viewing the problem is by

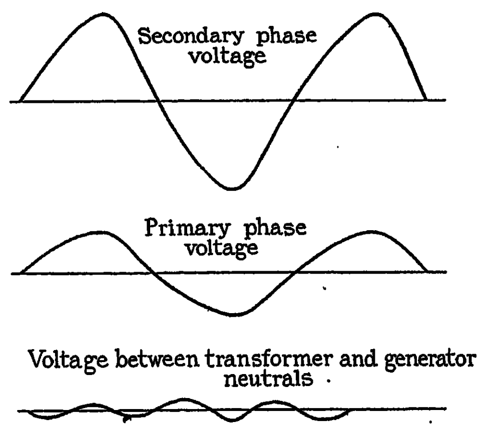

FIG. 11 (*a*).—Oscillograms of star-star-connected transformers with isolated neutrals, delivering balanced 4-wire load (1·5 A).

the aid of a vector diagram, as shown in Fig. 10. The various vectors in this diagram correspond exactly to the various curves shown in Fig. 9.

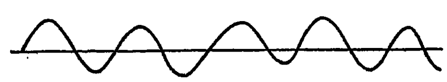

FIG. 11 (*b*).—Wave-form of voltage between transformer primary and generator neutral points. Transformer secondaries on open circuit.

It is, however, noteworthy that the primary flux wave, the primary reactive E.M.F., and the induced secondary E.M.F., cannot be entirely free from third harmonics, since these must be of sufficient value to

circulate the third-harmonic magnetizing current in the four-wire secondary circuits. It should also be noted that the magnitude of the third-harmonic magnetizing current circulating in the secondaries is inversely proportional to the impedances of the secondary circuits. Thus at no load the secondary induced E.M.F.'s, the primary reactive E.M.F. and the resultant flux in the core will all have maximum third-harmonic components, these decreasing as the load is increased, being absorbed in circulating the third-harmonic magnetizing currents through the secondary circuits. It is thus seen that in the case under consideration the voltage wave-forms are dependent upon the secondary load.

Figs. 11, 11 (*a*) and 11 (*b*) show a series of oscillograms taken on a group of three 2-kVA single-phase trans-

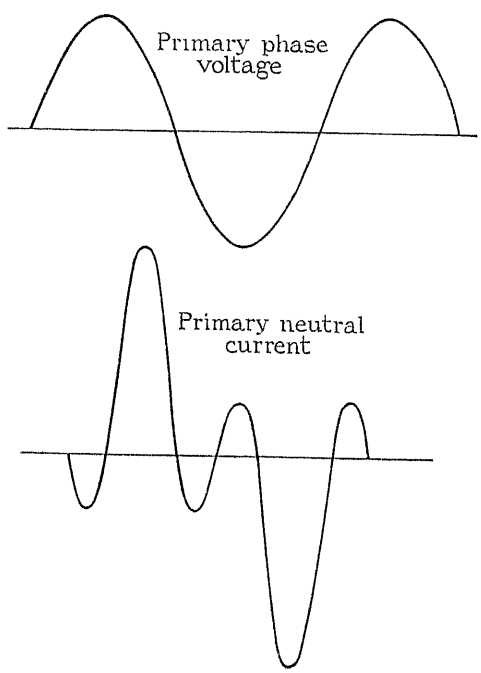

FIG. 12.—Oscillograms of star-star-connected transformer with primary and generator neutrals connected. Neutral current (R.M.S.) 1·82 A.

formers, both neutrals being isolated, and the secondary delivering a balanced four-wire supply. The supply pressure was practically sinusoidal. The full-load secondary current was 10 amperes, but even with a load of 1·5 amperes the harmonics in the waves had been largely damped down as shown in Fig. 11 (*a*). As the load is gradually decreased beyond this point, the harmonics in both primary and secondary phase voltages gradually increase, as does also the potential oscillation of the primary neutral, this being measured with respect to the generator neutral which is assumed to be stable. The oscillation reaches its maximum amplitude when the load is reduced to zero, as shown in Fig. 11 (*b*).

(*c*) *Primary neutral earthed.*—The effects of earthing the primary neutral at the transformer, the generator windings being insulated, is practically the same as earthing the generator neutral and keeping the transformer neutral insulated. The potentials of the various windings are tied to earth, but no third-harmonic magnetizing currents can flow. The effects are similar to those dealt with in Case 1 [(*a*) and (*b*)].

Where the transformer neutral is earthed on the system in which the generator neutral is earthed as well, however, different conditions are set up. There is

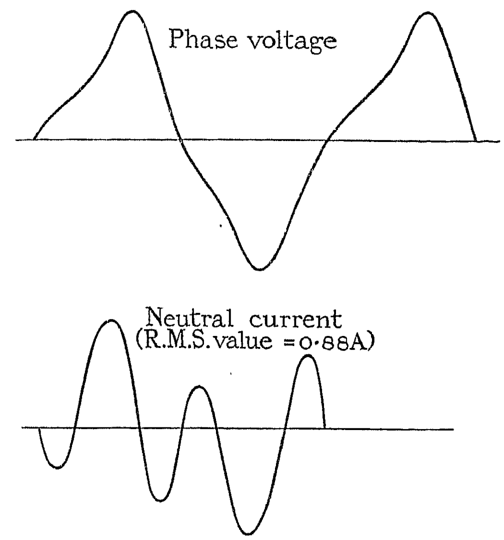

FIG. 12 (*a*).—Oscillograms of star-star-connected transformers with primary and generator neutrals connected. Neutral current (R.M.S.) 0·88 A.

now a closed path for the third-harmonic magnetizing currents to flow in the primary system. The magnitudes of these currents will depend to a considerable extent upon whether the windings are earthed solidly or through resistances. In the latter event they will be limited in value to an amount depending upon the value of the

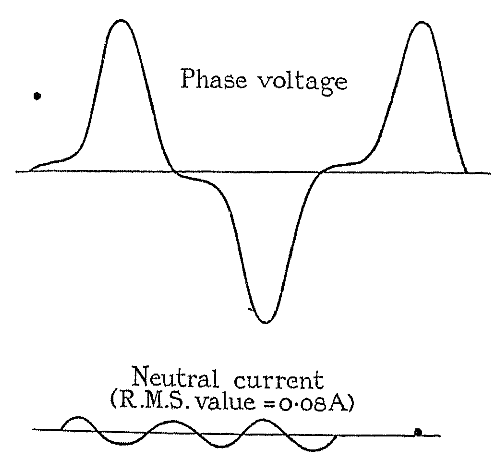

FIG. 12 (*b*).—Oscillograms of star-star-connected transformers with primary and generator neutrals connected.

earthing resistances. The triple-frequency oscillation of the neutral potential is very much reduced and may be brought down to a negligible value if the earthing device is of sufficiently low resistance. The advantage thus gained, however, may be more than counterbalanced in certain cases by the third-harmonic magnetiz-

ing currents setting up resonance on account of the line capacity. In many cases, therefore, this connection is dangerous and should be avoided.

A series of oscillograms is shown in Figs. 12, 12 (*a*), 12 (*b*) and 12 (*c*), illustrating the effect of connecting the generator and transformer primary neutrals together through resistances of various magnitudes. The transformers were the same as those used for Fig. 11, and were connected star-star, the supply pressure being again practically sinusoidal. The resistance in the primary neutral wire was varied between a minimum value and infinity, and the oscillograms refer to (*a*) primary phase voltage and (*b*) neutral-wire current. The fundamental component in the neutral current was due to lack of balance on the part of the individual transformers. This current at fundamental frequency was gradually eliminated as the resistance in the neutral wire was increased. The amplitude of the neutral third-harmonic current was gradually reduced simultaneously, but not to the same extent. The third

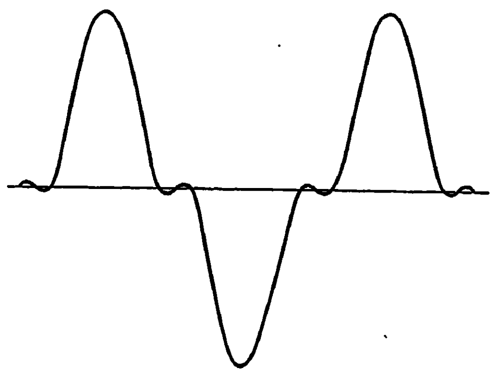

FIG. 12 (*c*).—Oscillogram of phase voltage. Neutral current zero.

harmonic in the phase voltage gradually increased as the resistance was increased, and became a maximum when the neutral wire was open-circuited. The ninth harmonic in the current is negligible in the present instance.

The effect of line capacity should also be considered; this is referred to in Case 6 (*c*).

CASE 2: STAR-STAR-TERTIARY DELTA CONNECTION.

Primary and secondary neutrals isolated.—When the ordinary star-star connection is applied to a three-phase shell-type or three single-phase shell- or core-type transformers, considerable third-harmonic voltages are induced in the windings due to the suppression of the third-harmonic magnetizing current in the two windings. These voltages may be of the order of 50 per cent of the fundamental at ordinary core flux densities, and may even become as high as 60 per cent in extreme cases (see Fig. 8).

The addition of the tertiary winding may be adopted for one or more of the following reasons:—

(1) To protect the transformer from excessive third-harmonic potentials.

(2) To stabilize the neutral potential.

(3) To prevent telephone interference in the lines and earth.

(4) To supply a load in addition to any of the above purposes, i.e. a condenser load for power factor improvement.

When used for the first-named purpose, the primary and tertiary windings act, from the point of view of magnetization, as a star-delta system (dealt with in Case 4). The flux wave will have a slight tendency towards being flat-topped, thus giving rise to slightly peaked voltages in both secondary and tertiary windings. In the latter case the fundamentals neutralize one another around the closed delta, but the third-harmonic components are virtually on short-circuit. The resulting third-harmonic currents will tend to supply the deficiency in the primary magnetizing current and will restore the flux wave almost to its normal shape. It is, of course, impossible that it should do this completely, as in this event there would be no harmonic E.M.F. generated in the tertiary, and the action would cease. The tertiary winding is designed to carry only the third-harmonic magnetizing currents (together with the ninth, etc.), and low leakage reactances of the primary and tertiary windings considered in combination are not essential. In fact it is desirable that these reactances should be high enough to limit to a safe value the circulating current produced in the tertiary by an accidental "line to neutral" short-circuit. In this event the voltage in one leg of the delta disappears, and the remaining two phases may set up a resultant voltage, acting round the closed tertiary circuit, sufficient to burn it out by means of current at fundamental frequency.

When a tertiary winding is employed for the purpose of stabilizing the potential of an oscillating neutral a different set of characteristics is desired. The oscillation of the secondary neutral potential is due to the presence of third-harmonic E.M.F.'s in the secondary phases, and these in their turn are due to the flattening of the flux wave. It is therefore desirable that the latter should be reduced to the smallest possible amount. The third-harmonic component of the magnetizing current, which is derived from the tertiary winding, should be set up with the least possible magnetic leakage, and the coupling between the primary and tertiary should be close. In this manner the deformation of the flux wave necessary to set up the required E.M.F. in the tertiary can be reduced to a minimum.

Telephone disturbances are due to harmonic currents circulating in lines or earth paths which run parallel to the telephone cables. In this connection the ninth harmonic may not be neglected. The interference is dependent upon the magnitude of the current and the length of the interfering line, and is only likely to take place on long transmissions when operating either with a fourth wire or with an earthed neutral, or, in other words, where there is a low-impedance path for the harmonic currents.

When a tertiary winding is used to supply load it practically devolves into an additional secondary, and the turns must be of sufficient cross-section to carry their own load currents at fundamental frequency, in addition to the magnetizing currents at harmonic frequency. In this connection a condenser load has

been suggested for the purpose of phase-advancing. From the point of view of protection from breakdown a looser coupling is now desired, with respect to both the primary and the secondary, so as to provide sufficient leakage reactance to withstand either a short-circuit on its own lines or on those of other windings. In any case a loose coupling is desired with respect to the secondary. The tertiary winding may be incorporated in the secondary by opening the neutral point of the latter and connecting the resulting three free ends to the three junctions of the auxiliary delta as shown in Fig. 13. In this way a saving in secondary copper may be brought about, since the third winding is usefully employed in carrying the secondary load current and in providing a portion of the secondary E.M.F., in addition to its other functions. The method suffers, however, from two disadvantages. There is no point available for direct earthing should the occasion arise, and there is a small phase displacement of the secondary line E.M.F.'s so that a transformer connected on this plan would not be capable of being paralleled directly with another one unless the angle of phase displacement were the same. This angle depends upon the relative number of turns per winding in the main secondary

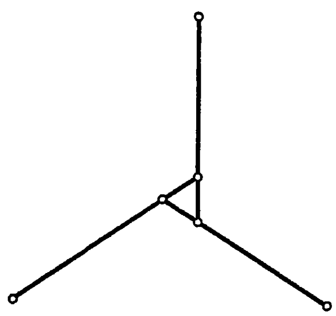

FIG. 13.—Interconnected tertiary winding.

and auxiliary delta windings, and lies between the extreme limits of 0° and 30°.

When the primary or secondary is connected in delta there appears to be no adequate reason for the introduction of a tertiary delta.

Oscillograms illustrating the effects of a tertiary delta are shown in Fig. 14, and serve to point out the smoothing effect of the auxiliary winding. The full-line curve in Fig. 14 (*a*) represents the voltage across the primary phases with the auxiliary delta opened, whilst the dotted curve shows the phase voltage with the auxiliary delta closed. The suppression of the harmonics is quite evident. The corresponding magnetizing currents are shown in Fig. 14 (*b*), the full-line curve again referring to the case where the delta was on open-circuit, and the dotted curve to the case where the delta was closed. The improvement in the primary magnetizing-current wave-form is again evident. In the latter case the auxiliary winding provides a portion of the M.M.F., and a current of irregular shape circulates around the closed delta in order to account for the difference between the two magnetizing currents in Fig. 14 (*b*). The magnetizing current circulating around the closed delta is shown in Fig. 14 (*c*). The small fundamental present in the wave is accounted for by the lack of balance of the various individual single-phase transformers. The oscillating voltage between the generator and primary neutrals is shown in Fig. 14 (*d*). With open-circuited delta (full line) the R.M.S. value of this voltage was 50 per cent of the R.M.S. phase voltage. This dropped to a negligible amount when the auxiliary delta was closed (dotted line).

In order to imitate the effects of a loose coupling between primary and auxiliary delta, reactance was

introduced into the latter. The oscillating voltage between generator and primary neutrals was considerably affected as shown in Fig. 14 (*e*), its R.M.S. value falling from 50 per cent to 20 per cent of that of the phase voltage. The loosely coupled tertiary delta is not so effective in damping out the voltage oscillation, but it is safer in the event of a fault.

Summary of star-star connections in order of preference.—(1) The best arrangement is with three-phase core-type transformers, the third-harmonic voltage being

reduced to a negligible value. The neutral may be either earthed or isolated. (2) With three-phase shell-type or three single-phase core- or shell-type transformers, the third-harmonic voltage being reduced to a negligible value, provided the transformer primary and generator neutrals are connected and they are fairly close together. This connection is quite satisfactory. (3) With three-phase shell-type transformers with tertiary delta the operating characteristics are superior to (1) and (2) if the tertiary delta has a low reactance, since the transformer operates as a star-delta transformer as regards magnetizing current. The cost of the tertiary winding solely for this purpose is, however, generally prohibitive. (4) With isolated neutrals, three-phase shell-type or three single-phase transformers of the core or shell type may give rise to harmonic voltages of as much as 50–60 per cent of the fundamental voltage. If they are provided with sufficient insulation to withstand the extra stresses set up there is no great objection, since the third-harmonic voltage does not appear between the lines. (5) With earthed neutrals the third-harmonic voltage may cause resonance with the line capacity and thus set up dangerous conditions. It is therefore not recommended.

Case 3: Star Interconnected-Star Connection.

(*a*) *Both neutrals isolated.*—There being no primary path for the third-harmonic magnetizing currents, this component is absent and the flux wave is correspondingly flat-topped. The primary phase voltage is peaked and the primary neutral is subjected to an oscillating potential. The six secondary windings also have third-harmonic voltages induced in them, but these cancel out in the two halves of each phase winding. Neglecting the other harmonics, therefore, the secondary phase voltage between line and neutral is sinusoidal. As there is no magnetization of the core from the secondary, there is no neutralizing of the flat-topped effect in the flux wave, such as occurs when the secondaries are connected in delta.

Whilst the trouble and possible danger of an oscillating neutral on the secondary side is removed, however, the effect appears again at the junctions of the two halves of each phase winding, for the potentials of these points oscillate about a mean value at third-harmonic frequency. This is not so troublesome as an oscillating neutral, and can be guarded against by the provision of adequate insulation. Moreover, the magnitude of the effect is only half as great as in the case of the plain star connections, for the two sections of the winding combining to bring about this result contain only half as many turns.

(*b*) *Generator and primary neutrals connected.*—This connection is similar to the one discussed in Case 1 (*c*), a greater or lesser amount of third-harmonic magnetizing current flowing in the primary circuit using the fourth conductor as a drain. The lower the resistance of the fourth wire or earth connections, the more closely will the flux wave approximate to the desired sine shape. There is no oscillation in the secondary neutral potential either with or without the fourth conductor, but the oscillation in the potentials of the mid-points of the secondary phases is very materially reduced by the additional connection, made either directly or by earthing. For the reasons already mentioned, however, this is not recommended.

(*c*) *Four-wire secondary.*—The provision of a fourth conductor on the secondary side does not affect the distribution of magnetizing current as it did with a plain star-connected four-wire secondary, as there is no resultant third-harmonic voltage set up in the secondary phase windings. The conditions are therefore the same as those in Case 3 (*a*).

Case 4: Interconnected Star-Star.

(*a*) *Both neutrals isolated.*—No third-harmonic magnetizing currents can flow in either primary or secondary, so that the flux wave is flat-topped. Third-harmonic E.M.F.'s will be induced in the secondary phases, giving rise to oscillation of the secondary neutral. Third-harmonic E.M.F.'s will also be induced in each half-phase of the primary, but these will cancel out between primary line and neutral, thus imparting to the latter a stable fixed potential. The potentials of the mid-points of the primary phases will oscillate as indicated in Case 3 (*a*). This oscillation, together with that of the secondary neutral, could be practically eliminated

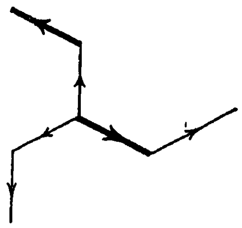

Fig. 15.—Showing impossibility of third-harmonic currents in interconnected primary.

by the introduction of a tertiary delta, but if this were done there would be no reason for interconnecting the primary windings.

(*b*) *Generator and primary neutrals connected.*—Assuming the generator supply pressure to be sinusoidal, no third-harmonic magnetizing current will flow, and the third-harmonic voltages in the two halves of each phase winding will balance each other. That no third-harmonic magnetizing current can flow can be seen by considering what would happen if it did. When the third-harmonic current is flowing through one half of the winding on any particular core, it is flowing in the *reverse* direction in the other half which is connected to the next phase (see Fig. 15), and as these currents are in phase with one another, but flowing through the winding in opposite directions at any given instant, they would produce no resultant M.M.F. on the core. As they cannot be set up directly by the impressed E.M.F., and as there is no cause for their self-inducement, they do not exist. Also, since there is no potential difference between the neutral points of the generator and the transformer primary, there is no third-harmonic magnetizing current flowing into the neutral point of the transformer primary, and hence through the windings.

The primary neutral potential is therefore stable and there is no need for the primary fourth conductor. The secondary neutral potential will oscillate as before.

Should the generator phase winding possess a third harmonic, however, quite a different set of conditions occurs. A third-harmonic current will now be forced round the three circuits consisting of generator phase winding, line, transformer primary phase windings and neutral return. The corresponding ampere-turns of each half of the transformer phase winding will now be neutralized by the ampere-turns of the next phase wound on the same limb, so that to all intents and purposes the transformer primary becomes non-inductive to the third-harmonic currents. The generator third-harmonic voltage is thus virtually on short-circuit, the current being limited only by its own impedance and the resistance of the external circuit. The current may therefore rise to a dangerous value, so that this connection should not be employed. Single earthing at either generator or transformer neutral is not, however, condemned.

(c) *Four-wire secondary.*—With this connection third-harmonic currents can circulate in the secondary circuit, thus making good the deficiency in the primary magnetizing current. The deformation of the flux wave will be reduced, although it cannot be eliminated, and the secondary neutral potential will be largely stabilized. The extent to which the latter is effected is dependent upon the magnitude of the secondary load, as this determines to a large extent the impedance offered to the flow of the third-harmonic currents. It will also be noticed that the distortion of the flux wave will decrease as the (lagging) power factor of the load is improved, since the presence of inductance in the load circuits tends to damp out the harmonics in the current wave.

The primary neutral potential is stable as before.

Comparison of the interconnected star and the tertiary delta.—It would appear from the foregoing that the interconnected star is unlikely to find an extensive field for the suppression of harmonic troubles. Due to the 30° phase displacement between the phase and line voltages, 15½ per cent more copper becomes necessary as compared with the straight star, in order that both transformers may be placed on the same basis as regards kVA rating. In addition to this disadvantage, the interconnection should be confined to the lower-voltage side, owing to the difficulties experienced in the interconnection of high-voltage windings. The cost per kVA of the interconnected transformer is increased, due to both reasons, whilst the insulation difficulties will possibly increase the liability to breakdown. Moreover, these disadvantages do not appear to be counterbalanced adequately by the advantages. Whilst the harmonics in the voltage waves are cancelled out in the two halves of the windings, the junctions of the windings oscillate, and the method of obtaining a sine wave of voltage seems to be inherently unsound.

On the other hand, the tertiary winding suppresses the third-harmonic voltages in the phases by providing for the sinusoidal magnetization of the core, i.e. by removing the cause of the third-harmonic troubles. Although the phase-voltage wave will always have a third-harmonic component, as previously explained, this will be very small since its only function is to circulate the harmonic magnetizing current in the tertiary delta. As in the case of the interconnected star, additional copper is required, but it is probable that in the case of the tertiary delta the extra cost represents a much sounder investment. The factor of safety is probably higher than in the case of the interconnected star, but the tertiary winding will have to be insulated for high potentials. The cost of the independent tertiary is, however, prohibitive, unless it is designed to supply a load also, and in this latter respect the claims of the interconnected tertiary cannot be ignored in those cases where the connection can be adopted. In this case the cost neither of insulation nor of copper is appreciably increased, for the whole of the tertiary winding normally operates at low potentials to earth. This connection, so far as the authors are aware, does not appear to have been made use of for the suppression of third-harmonic troubles, in spite of the fact that it seems to be particularly suited to certain cases, such as the provision of an alternative to the straight star-star connection for transforming up the generating pressure for transmission purposes. In this case the provision of the interconnected tertiary winding allows the good inherent characteristics of the star-star windings to be retained, and at the same time the dangerous conditions already referred to, consequent upon the presence of third-harmonic voltages acting in the transformer phases, appear to be averted.

From the point of view of stabilization of the neutral, the interconnected star winding is superior to the tertiary delta, since complete stabilization is afforded. Even in this case, however, the interconnected tertiary can become a powerful rival as, due to the close coupling, practically complete stabilization can be claimed, whilst the latter does not suffer from the disadvantage of mid-point oscillations. Where the secondary neutral is required for four-wire service or for earthing, there would appear to be no serious objection to placing the tertiary delta on the primary side. Expressions of opinion from designers concerning the utility of this connection would be very valuable.

Case 5: Star-Delta Connection.

(a) *Primary neutral isolated.*—As before, the primary magnetizing current drawn from the line cannot contain harmonics which are multiples of three, and in consequence the flux wave will have a tendency towards being flat-topped. The reactive E.M.F. in the primary phases and the induced secondary E.M.F.'s will as a result be peaked to a certain extent. The sine fundamental components of the secondary phase voltages add up to zero, when taken round the delta, but the third-harmonic components, being in phase with one another, are free to produce a magnetizing current circulating round the secondary delta. This current, neglecting losses, lags 90° behind the third-harmonic voltage, providing the ampere-turns for the production of a flux which will very nearly suppress the third-harmonic flux set up by the primary magnetizing current. These two opposing third-harmonic fluxes really only exist, of course, in their resultant. Another way of viewing the question is to regard the fundamental waves as operating on open-circuit or on normal load, whilst the third-harmonic

waves are operating on short-circuit and are thus very effectively damped down.

It is therefore seen that the generator will provide the fundamental, the transformer primaries the fifth, seventh, eleventh, etc., harmonics, whilst the secondary delta will provide the third, ninth, etc., harmonics of the currents necessary for the normal magnetization of the cores.

The mechanism of the operation is illustrated in Fig. 16, in which all the harmonics with the exception of the third have been neglected. In the left-hand group of curves, I_m represents the sinusoidal magnetizing current, split up into two components, I_f and I_h. The major component, I_f, consisting of fundamental and third harmonic is the magnetizing current necessary to produce the main sinusoidal primary flux represented by Φ_f in the right-hand group of curves. The harmonic component, I_h, gives rise to the hypothetical third harmonic flux represented by Φ_h. (It would also give rise to further harmonics, but these are neglected.) The main flux, Φ_f, induces the fundamental secondary E.M.F., E_f, and the harmonic flux, Φ_h, induces the harmonic E.M.F., E_h. The latter, being short-circuited, does not appear as a P.D. at the terminals and is absorbed in the windings. It does, however, give rise

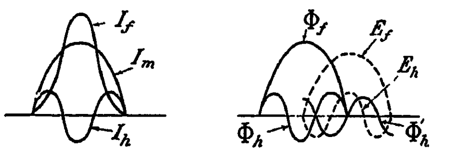

FIG. 16.—Magnetization from secondary delta.

to ampere-turns, which set up the hypothetical harmonic flux represented by Φ_h'. This is in direct phase opposition to the other hypothetical harmonic flux, Φ_h, the resultant of the two being almost nil. If all losses and magnetic leakages were neglected, the two would exactly counterbalance each other, the flux wave would be sinusoidal, and the secondary induced E.M.F. would contain no harmonics. Actually there is a minor flattening of the flux wave.

(*b*) *Generator and primary neutrals connected.*—In this case a closed path is provided for the third-harmonic components of the magnetizing currents, and these, in consequence, may be drawn from the line. The path provided consists of the generator phase winding, line conductors, transformer primary winding and neutral conductor, the last-named carrying a harmonic current equal to the sum of the third-harmonic components in the line conductors. It will be seen, therefore, that the third-harmonic current necessary for the normal magnetization of the core can flow in both the primary and secondary windings. In regard to the primary, however, since this current must circulate through the impedances of the conductors and the generator phase winding, it follows that its magnitude may be insufficient to produce, together with the fundamental current, a true sine wave of flux. The latter will therefore contain a third-harmonic component producing a certain amount of flattening of the wave. Due to this the primary reactive E.M.F. and the secondary induced E.M.F. will be peaked to a corresponding degree, and the third-harmonic components of the secondary voltage, operating under practically short-circuit conditions, will circulate a triple-frequency magnetizing current around the closed delta. As the impedance of the secondary delta path will be much lower than that of the corresponding primary path, it follows that the greater part of the third-harmonic magnetizing current will circulate around the secondary delta, and practically normal magnetization of the core will be effected. The flux and voltage waves will therefore be approximately sinusoidal.

(*c*) *Generator and primary neutrals earthed.*—This case is similar to the previous one, but the impedance of the paths of the third-harmonic magnetizing currents circulating in the primaries will be increased, since the resistance of the earth return will be greater than that of the fourth conductor. As a result, the secondary delta will carry a still greater proportion of the third-harmonic magnetizing current. If the generator neutral point be earthed through a resistance or reactance, the effect is still further to increase the triple-frequency current in the secondary, at the same time reducing the corresponding primary current. The limiting case is reached when the generator neutral is isolated, the whole of the third-harmonic magnetizing current now circulating around the secondary delta.

CASE 6: DELTA-STAR CONNECTION.

(*a*) *Secondary neutral isolated.*—Called into being by the peculiar shape of the *BH* curve, the third-harmonic magnetizing currents cannot flow back along the primary lines, but they can and do circulate around the primary delta, which provides a closed path for them. The complete magnetization of the core can thus be effected from the primary side, with the result that a sine wave of flux is set up. The induced E.M.F.'s are, therefore, also sinusoidal and the secondary neutral potential is stable. Even here a portion of the fifth, seventh, etc., harmonic components of the magnetizing current may flow in the secondary, if the relative impedance of the two sides is favourable to this.

(*b*) *Four-wire secondary.*—With this connection there is a closed path in both primary and secondary circuits for the third-harmonic magnetizing currents, and these flow in both sets of windings. The complete magnetizing current necessary for the establishment of a sine wave of flux does not come solely from the primary, and therefore there must be a certain amount of flattening of the flux wave, brought about by the introduction of a small third-harmonic component. This gives rise to small third-harmonic E.M.F.'s which make their appearance in the secondary phases. These in their turn set up third-harmonic currents which flow through the secondary phase windings of the transformer, the secondary line, and the load circuits, their arithmetical sum returning by way of the fourth wire. The impedances of these paths being relatively high compared with the impedance of the corresponding paths in the primary circuit, consisting of the phase windings forming the closed delta, it follows that the third-harmonic magnetizing currents flowing in the secondary will be small compared with those flowing in the primary circuit. The ratio which these two bear to one another is also

dependent upon the value of the secondary load, on light loads the secondary third-harmonic magnetizing current being almost negligible. In any case the bulk of this triple-frequency current circulates in the primary delta, with the result that the flux wave is almost sinusoidal. Again, the shape of the flux wave depends upon the magnitude of the secondary load, the deformation becoming less with decrease in load. Small third-harmonic E.M.F.'s are induced in the secondary phases, giving rise to the secondary third-harmonic magnetizing currents, and causing a certain amount of oscillation in the potential of the secondary neutral point. This oscillation increases somewhat with increase of load.

(*c*) *Secondary neutral earthed.*—This connection is similar to the previous case, but if the insulation resistance of the load is high, the whole of the third-harmonic magnetizing current necessary for the normal magnetization of the core will circulate in the primary delta.

If, however, the load be star-connected and its neutral point earthed, the connection becomes a variant of the previous case. The third-harmonic magnetizing currents circulating through the secondary phases, lines, load and earth, will be negligibly small owing to the resistance occurring in and adjacent to the earth plates. This connection would appear to be suitable for stepping up the generating pressure to a higher pressure (33 000–66 000 volts) for the transmission of large amounts of power to a distant load centre. In this case, where very high voltages or large capacities, or both, are involved, it is interesting to consider the effect of harmonics should the insulation near the neutral point of the star-connected primary of the transformer at the receiving end fail. In the event of this transformer being equipped with Merz-Price circulating-current protective gear, at least 5 per cent of the phase windings near the star point will usually be unprotected. If the coil insulation fails within the 5 per cent boundary, the protective gear will not operate and in consequence a completely closed circuit exists for the third-harmonic magnetizing currents, and their sum will circulate between earthing connections. The flux wave will then become slightly flat-topped, thus giving rise to the necessary third-harmonic voltage across the secondary phases for this purpose. It should be noticed that the harmonic voltage is free to circulate a third-harmonic capacity current and this will be developed by the capacity reactance of the circuit. Since the effect of the third-harmonic magnetizing currents is to tend to convert the flat-topped flux wave into a sine wave, it follows that the effect of the third-harmonic capacity current is to do the reverse, by endeavouring to set up a third-harmonic flux wave in phase with the fundamental flux wave. In other words, it will tend to make the flux wave more flat-topped and the voltage waves more peaked, as shown in Fig. 17.

It should be appreciated that the "flat-topping" effect of the capacity currents is nine times as great per volt as the "peaking" effect of the magnetizing currents.

The vector diagram in Fig. 17 also serves to illustrate a rather curious condition which may arise. Suppose that the third harmonic of the capacity current drawn from the supply is equal in magnitude to the third-harmonic current required for the normal magnetization of a transformer connected at the receiving end of a line. It will be seen that, neglecting the higher harmonics, no third-harmonic currents will be drawn from the generator, and in consequence the current wave at the sending end of the line will be sinusoidal. The amplitude of the third harmonic of the capacity current will, however, decrease uniformly (approximately) as the distance from the generator increases, whilst that of the third-harmonic magnetizing current will be constant. The distortion of the current wave will clearly increase uniformly and become a maximum at the receiving end of the line. As no harmonic currents are drawn from the generator it would appear that the capacity of the line serves a useful function in supplying the harmonic magnetizing current required by the transformer core, or, in other words, the conditions at the generating end are such as to produce complete current resonance at third-harmonic frequency. In this case the effect of earthing a circuit at more than one point will be considered, as this has been suggested

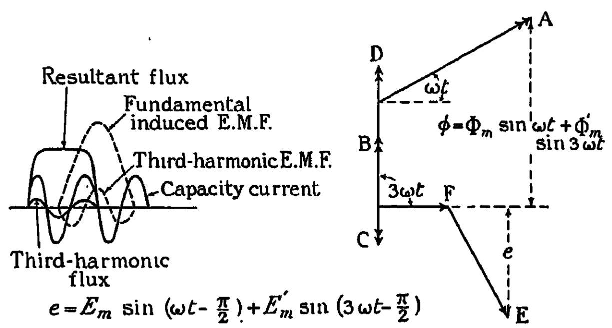

FIG. 17.—Effect of capacity currents.

A = Fundamental flux due to primary magnetizing current.
B = Third-harmonic flux due to primary magnetizing current.
C = Third-harmonic flux due to third-harmonic component of secondary E.M.F.
D = Third-harmonic flux due to secondary capacity currents.
E = Induced fundamental E.M.F.

in the case of two power houses tied together by means of an underground interconnector. If the pressure is stepped up at both ends and the high-voltage secondaries of both transformers are earthed, the third-harmonic components of the capacity currents will be relatively large, and a dangerous set of conditions may result due to the consequent large third-harmonic voltages across the transformer secondary phases.

It is pleasing to consider that in this instance the Postmaster-General's requirements in regard to earthing appear to be in line with the interests of power supply engineers.

CASE 7: DELTA-DELTA CONNECTION.

It is here possible for the third-harmonic magnetizing current to circulate freely in both closed deltas, so that as far as this component is concerned the core is magnetized from both primary and secondary. In order to induce the necessary secondary harmonic E.M.F. a certain flattening of the flux wave will be brought about, but this will be minimized by the secondary magnetizing effect, so that the resultant distortion is but small.

The third-harmonic magnetizing currents on the two sides will depend upon the relative impedances of the two deltas, being greater in the delta of the lower impedance. Assuming that these impedances are proportional to the square of the ratio of transformation, and taking into consideration the relative number of turns, it follows that the harmonic magnetizing ampere-turns will be equal on the two sides, neglecting losses and magnetic leakage.

CASE 8: TEE-TEE CONNECTION.

(a) *Both neutrals isolated.*—It will be assumed that the generator supplies a pure sine wave of E.M.F. to the primary of the transformer, and therefore it would appear that owing to a deficiency in the third-harmonic magnetizing current there will be a distortion of the flux waves in both of the magnetic cores. The fundamental primary currents flowing along *cd* and *bd* (see

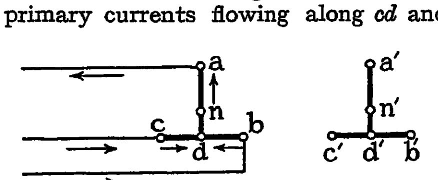

FIG. 18.—Tee-tee connection.

Fig. 18) are 120° out of phase with each other, or the fundamental primary currents flowing along *cd* and *db* are 60° out of phase with each other. Let each of these be imagined to produce its own sine wave of flux, together with its own flat-topped third-harmonic flux.

There are represented in Fig. 19, which also shows the two flat-topped fluxes, Φ_{cd} and Φ_{db}, due to the ampere-turns operating on *cd* and *db* respectively. The flux Φ_{cd} consists of a fundamental component, Φ_{cd1}, and a

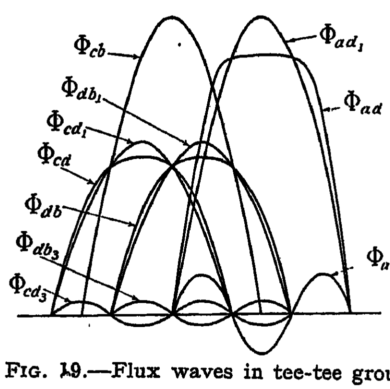

FIG. 19.—Flux waves in tee-tee group.

harmonic component, Φ_{cd3}. Similarly, Φ_{db} consists of the components Φ_{db1}, and Φ_{db3}. The final resultant of Φ_{cd} and Φ_{db} shows a sine wave of flux, Φ_{cb}, neglecting higher harmonics, this being 30° out of phase with each fundamental component, for the two harmonic fluxes neutralize each other. The latter, however, cause harmonic E.M.F.'s to be induced in the windings *cd* and *db*, and as the harmonic fluxes are equal and in exact phase opposition, so will be these harmonic E.M.F.'s. The point *d* will therefore oscillate at triple frequency. The fundamental voltages induced in *cd* and *bd* are 120° out of phase, but the third-harmonic voltages are in phase. As far as the latter are concerned the points *b* and *c* are equipotential.

Turning to the other winding, the primary fundamental current flowing along *ad* is 120° out of phase with that in *cd*. The flux due to *ad*, therefore, is 120° out of phase with the hypothetical flux due to *cd*, or 90° out of phase with the flux due to *cb*. This flux, Φ_{ad}, is assumed to be flat-topped to a certain extent, owing to a deficiency in harmonic magnetizing current. The third-harmonic flux, Φ_{ad3}, is in phase with the fundamental flux, Φ_{ad1}, due to ad_1, and therefore is in phase with the harmonic fluxes due to *cd* and *bd*. It thus appears that the harmonic E.M.F.'s induced in *cd*, *bd* and *ad* are all in phase with each other. The magnitudes of these harmonic E.M.F.'s are proportional to the products of flux and turns. In the case of *ad* both the turns and the flux are $\sqrt{3}$ times as great as in the case of *cd* and *bd*, and therefore the harmonic voltage induced in *ad* is three times the value of the corresponding voltage induced in *cd* or *bd*.

It is thus seen that whereas the "tee" system of connections is completely symmetrical as regards the fundamentals, it exhibits polarized symmetry only, when considered with reference to the third harmonics. From the latter point of view the points *c*, *b* and *n* are symmetrical and equipotential.

In the transformer secondaries, a third-harmonic voltage appears between lines *a′* and *b′*, none between *b′* and *c′*, and one equal and opposite to the first named between lines *c′* and *a′*. These unbalanced third-harmonic voltages produce unbalanced third-harmonic currents flowing round the secondary circuit.

Similar unbalanced reactive E.M.F.'s are set up in the primaries, causing a third-harmonic current to flow out by line *a*, this splitting up into two equal components at the neutral point of the generator and returning to the transformer by lines *c* and *b*. These currents, indicated by the arrows in Fig. 18, give rise to no resultant action on the winding *cb*, because their respective ampere-turns neutralize each other. The resultant sine wave of flux due to *cb* is therefore unaffected, but these currents will modify to a certain extent the magnitude of the potential oscillation of the point *d*. The third-harmonic current flowing in the winding *da* tends to eliminate the flat-topping harmonic in the flux wave by opposing Φ_{ad3}, but it cannot entirely neutralize it. The transformer does, however, attempt to supply its own magnetizing current, in view of the fact that the supply fails to do this completely.

The resultant fundamental ampere-turns acting on *cb* and on *ad* are exactly equal, for the fundamental currents are equal and the greater number of turns on *cb* is compensated for by the fact that the ampere-turns acting on *cd* and *db* are 60° out of phase with each other. It follows, therefore, that if the magnetic cores are the same and if *ad* is wound with 86·6 per cent of the turns of *cb*, the two fluxes are the same as far as the fundamental component is concerned. There is a slight difference due to the harmonic component of the flux.

In actual practice it is usual to make both windings alike, the additional 13·4 per cent of turns extending

beyond the point d. The far end of the winding is left open-circuited, and this point also is subjected to a certain oscillating potential.

The harmonics in the magnetizing currents and the potential oscillations set up are only of importance when a fair degree of saturation exists in the magnetic cores. If the transformers are worked on approximately the straight-line portion of the BH curve (say up to $B = 10\,000$ lines per cm^2), the effects will be inappreciable, but as the flux density is raised beyond this point they become more and more apparent.

The waves shown in Fig. 20 (*a*) and (*b*) illustrate these conditions. They refer to a small 6-kVA group normally operating on 100 volts, 50 cycles, with a maximum flux density of 10 000 lines per cm^2, but

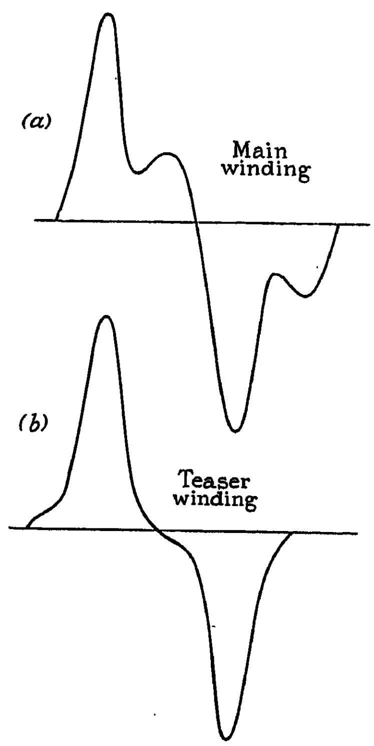

FIG. 20.—Magnetizing currents with tee-tee connections.

overrun so as to raise the maximum flux density to 14 000 lines per cm^2. With the primary system isolated from earth and the secondary on open circuit, Fig. 20 (*a*) represents the magnetizing current in the main winding and Fig. 20 (*b*) that in the teaser winding. When run on the normal voltage the waves exhibited similar characteristics but the harmonics were not so pronounced. The oscillations of the P.D. across various parts of the system also exhibited evidences of harmonics, but these were not of any practical importance. Considered as a whole, the harmonics are of much less importance than in the case of the star-star system of connections.

(*b*) *Both neutrals isolated. Secondary delivering four-wire supply.*—From what was said concerning the previous case, it will be seen that no harmonic currents will flow between the lines connected to the two ends of the 100 per cent winding and the neutral, for all three of these points are equipotential with reference to this harmonic. There is a third-harmonic difference of potential between the third line and the neutral point, however, and this will cause a third-harmonic current to circulate in this part of the secondary system, the currents in line wire and neutral being equal and opposite in phase. The value of this current will depend upon the magnitude and character of the load, in view of the fact that resistance, inductance and capacity affect the harmonic differently. This current will tend to neutralize the third-harmonic flux and will react in such a manner as to lessen the distortion of the resultant flux wave. This lessens the value of the induced third-harmonic E.M.F. and so the action tends towards a stable set of conditions. In the same way the unbalanced third-harmonic currents in the primary circuit are minimized. The system as a whole is still unbalanced, but to a lesser degree than in the former case.

(*c*) *Both neutrals isolated. Three-wire secondary line possessing appreciable capacity.*—It is interesting to consider the special case of a step-up transformer feeding a transmission system either underground or overhead in which capacity between cores and to earth, or alternatively between lines, is appreciable. There will be triple-frequency capacity currents flowing between lines a and b, and a and c, but none between lines b and c. The phase of these currents can be determined by reference to Fig. 19. The resultant third-harmonic E.M.F. acting between a and b (see Fig. 18) is the same as the third-harmonic E.M.F. between a and n, for there is no third-harmonic P.D. between n and b. This E.M.F. lags behind the flux Φ_{ad_3} by 90°, but as the resulting capacity current leads its E.M.F. by a corresponding angle, it follows that this current tends to set up a flux in phase with Φ_{ad_3}. In other words, it accentuates the magnetic distortion of the flux Φ_{ad}. The third-harmonic currents flowing out of lines b and c are equal in magnitude and phase, but exactly in phase opposition to the third-harmonic current flowing out of line a. Reference to Fig. 19 will show that these currents will tend to magnify the distortion in the flux, Φ_{db}, and to minimize it in the flux Φ_{cd}. The general effect is thus seen to unbalance still further the current and voltage relations in the whole system.

(*d*) *Generator and primary neutrals connected.*—The addition of a connection between the generator neutral and the transformer primary neutral will largely stabilize the potential of the latter point, and will cause a triple-frequency current to circulate between the line a and the neutral conductor. This will partially restore the distorted flux wave to its ideal sine shape, and will, to a corresponding extent, minimize the unbalanced third-harmonic voltages and currents in the secondary circuit.

If the neutrals are linked by means of earthing connections, either solidly or through resistances or reactances, then the stabilizing effects will not be so great, on account of the additional impedance offered to the third-harmonic currents.

CASE 9: SCOTT CONNECTION.

In the first place it will be assumed that the three-phase side is the primary, its neutral point n (see Fig. 21)

isolated, and that it is supplied from a generator giving a pure sine wave of E.M.F. The fundamental three-phase currents are balanced. As has already been shown, the flux wave due to the winding *ad* is distorted and exhibits the familiar flat-topped appearance, although not to any great extent. It follows, therefore, that while the induced E.M.F. in the secondary winding *c'b'* is approximately sinusoidal, that in the winding *a'd'* is peaked. The two secondary phases are not quite similar. When the group is placed on load a third-harmonic current will flow in the phase *a'd'* and this will tend to wipe out the third-harmonic flux in the core.

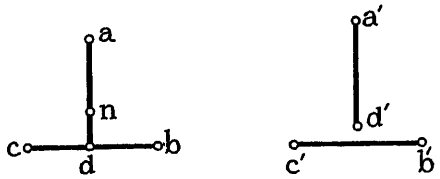

FIG. 21.—Scott connection.

The general tendency is to stabilize the primary potentials. A load of poor power factor is not so effective in this connection, as the presence of inductance in the secondary system tends to damp out the harmonic currents. Secondary inductance also alters the phase of the distorting flux harmonic.

When the three-phase primary operates with an earthed neutral, the generator neutral also being earthed, the case is similar to the plain tee-tee transformation already dealt with.

If the two-phase side is made the primary, the flux waves in both cores will be similar, and, since there is no inherent objection to the passage of third-harmonic currents, the flux waves will be sinusoidal. As a result no third-harmonic E.M.F.'s will be induced in the three-phase secondaries and, neglecting higher harmonics, the neutral potential will be stable. The question as to whether the phases are linked or independent on the two-phase side is immaterial.

CASE 10: VEE-VEE CONNECTION.

This system of connections is also unbalanced from the point of view of the third harmonic. If the primary

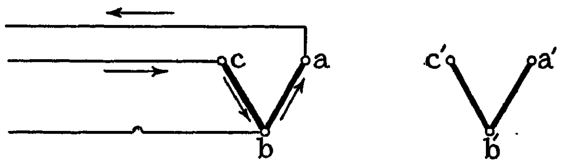

FIG. 22.—Vee-vee connection.

applied E.M.F. is sinusoidal in character, no third-harmonic magnetizing current will be supplied directly on account of this E.M.F., with the result that the two flux waves will be slightly flat-topped. The reactive E.M.F.'s in the windings *cb* and *ba* (see Fig. 22) will therefore contain third harmonic components tending to peak the respective waves. These harmonics will be equal in magnitude and will be exactly in phase, since the fundamentals are 120° out of phase. It follows, therefore, that there will be no resultant third-harmonic current flowing in the line *b*, but that a third-harmonic current will flow in each of the other two lines, these currents being equal and opposite.

Another way of looking at the problem is to consider the two lines connected to *c* and *a* respectively, together with the appropriate generator windings and the connecting lines, as forming the third circuit of a closed delta around which third-harmonic magnetizing currents can circulate. Owing to the fact that the impedance in the present case is greater than if a simple closed delta were employed, the third-harmonic magnetizing currents must fall short of the value requisite for pure sinusoidal magnetization. The flux waves cannot be entirely restored to their ideal shape, for in that event the third-harmonic magnetizing current would be reduced to zero. A reduction in the impedance of the circulating path would tend to increase the magnitude of the

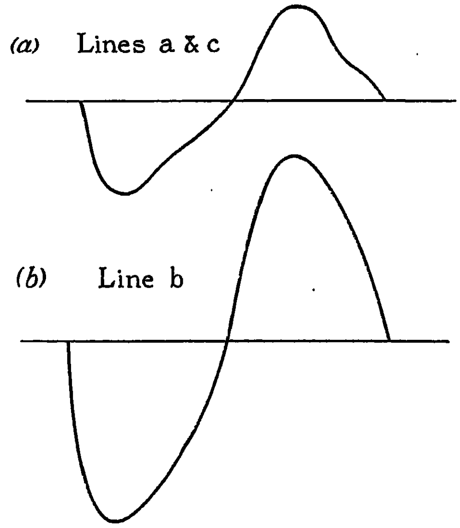

FIG. 23.—Magnetizing-current waves with vee-vee connections.

circulating harmonic current. This in its turn tends to reduce the flattening of the flux wave and so to reduce the magnitude of the third-harmonic E.M.F. The effect on the third-harmonic current, of reducing the impedance, is thus a differential one, but a low-impedance path does correspond to a closer approximation to sinusoidal conditions than a high one.

In the same way a circulating third-harmonic current will flow in the secondary system, in the lines connected to *c'* and *a'*. This current will also be determined to a great extent by the magnitude and power factor of the load, but again its tendency is to restore stable sinusoidal conditions.

With low or medium flux densities these effects are of small moment, but as one of the chief applications of this system of connections is for the starting apparatus used in conjunction with motors, first cost is an important consideration and higher flux densities are generally employed, particularly in view of the short-time rating usually adopted.

Oscillographic records (taken on two of the three

single-phase transformers used for the star-star tests) show that no appreciable distortion was introduced into the phase voltage, even when the group was worked at 40 per cent above normal pressure. The magnetizing currents naturally showed more distortion than when operated on normal voltage. Fig. 23 [(*a*) and (*b*)] shows examples of these magnetizing currents, Fig. 23 (*a*) representing the magnetizing current supplied to *a* (which was the same as that supplied to *c*) and Fig. 23 (*b*) that supplied to *b*. The latter wave shows a negligible amount of distortion, which was to be expected, whilst the former contains a considerable third harmonic.

Six-Phase Systems.

Case 11: Star Double-Star Connection.

There will be a certain amount of oscillation of the primary neutral potential, but it will be considerably less than in the case of the ordinary three-phase star-star transformation with both neutrals isolated, for closed paths for the third-harmonic magnetizing currents are found in the six-phase secondary.

Considering first the case where the primary neutral is isolated, the flux wave must exhibit a certain amount of flattening, on account of the usual absence of third-harmonic current in the primary, thus giving rise to the familiar peaked voltage wave in the secondary windings. Adjacent secondary phases being displaced by 60°, the third harmonics are all 180° out of phase with each other, or, in other words, are in exact phase opposition. Closed paths are therefore provided for the third-harmonic magnetizing currents to circulate in the secondary, phases 2, 4 and 6 forming the return paths for the currents in phases 1, 3 and 5. If the electrostatic capacities and insulation resistances between lines and to earth be uniform, the neutral point will take up a stable potential, but the line potentials will exhibit third-harmonic phenomena and will oscillate slightly due to the peaked phase voltages. The case is similar to the three-phase star-star transformation with four-wire secondary, except that three lines together with their respective phases act as the returns for the other three, instead of one conductor dealing with the summation of the three. If the electrostatic capacities and insulation resistances be unbalanced, the neutral will oscillate to a minor degree, but this will generally be unimportant. It is thus seen that the transformer cores can receive a certain amount of harmonic M.M.F. from the secondary system, making up to a large extent the deficiency in the primary currents. These "peaking" secondary ampere-turns tend to remove the flat tops of the flux waves, and reduce to a large extent the third-harmonic voltages in both primary and secondary. The effect is still further reduced in the case of a three-phase core-type transformer, on account of the interaction of the various magnetic fluxes. The flux waves, however, would only be restored to their ideal shape if the secondary system possessed zero impedance. In an actual case this is not quite achieved, but the resultant disturbance is small.

If the secondary neutral point is earthed, there will be no current in the additional circuit provided and, apart from electrostatic and electromagnetic balance, there is no change.

If the primary neutral point is earthed, capacity currents between primary lines and earth may, in part, provide the deficiency in the primary magnetizing current, as explained in Case 6 (*c*), thus helping to stabilize the neutral potential and to minimize the third harmonics in the secondary.

Case 12: Star-Diametric Connection.

If electrostatic and leakage balance is preserved, there is no difference between this and the previous case, for no current flowed into or out of the star point when it was earthed, and in the present instance the mid-point of each secondary takes up the same potential, with respect to both the fundamental and the third harmonic. It appears, therefore, as if the additional expense involved in bringing out the extra tappings is not justified, except for some special purpose such as for dealing with heavy out-of-balance currents in the case of a three-wire rotary converter. If these out-of-balance currents are not too large they can be balanced on one secondary winding alone.

Case 13: Star Double-Delta Connection.

This arrangement is practically the same as that discussed in Case 5, where a three-phase secondary was connected in delta. The third-harmonic magnetizing currents circulate round both secondary deltas, each of which provides half the third-harmonic M.M.F. for the magnetization of the transformer cores. The flux wave is almost restored to the sine shape, and the oscillation of the primary neutral potential is practically eliminated.

Case 14: Star-Double Interconnected Star Connection.

With this arrangement a considerable oscillation of the primary neutral potential would be met with, assuming it to be unconnected with the generator neutral. Due to the absence of primary third-harmonic currents, the flux wave would exhibit a certain amount of flattening and the phase voltage would be correspondingly peaked. With the interconnected-star arrangement there is no oscillation of the neutral potential, although the six mid-point tappings would oscillate. The adjacent phases are 180° out of phase with one another with respect to the third harmonic, but there is no third-harmonic circulating current since the resultant third-harmonic E.M.F. between line and neutral is zero in every case. There is therefore no damping of the primary neutral oscillation, as in the case of the plain double star. In spite of the added cost of bringing out the intermediate tappings, the interconnected double star is definitely inferior from the third-harmonic point of view.

Case 15: Star-Double Star-Tertiary Delta Connection.

There is no case for the introduction of a tertiary delta where six-phase secondaries are employed, for the third-harmonic currents can circulate in the secondaries,

thus damping down the osculation of the primary neutral.

Case 16: Interconnected Star Six-Phase Secondaries.

The advantage of an approximately stable neutral, one of the great points in favour of interconnected windings, is here obtained quite independently of the primary, as shown above, so that even when the primaries operate on a relatively low voltage there is no reason to adopt this costly arrangement.

Case 17: Delta-Double Star and Delta-Diametric Connections.

This arrangement is practically the same as Case 6. The flux wave is sinusoidal and there is no oscillation of the secondary neutral potential. Since closed third-harmonic paths exist in the secondary as well as in the primary, a portion of the third-harmonic M.M.F. will be supplied by each set of windings, but by far the greater proportion will be provided by the primary on account of the relative impedances in the two cases. The provision of an additional connection to the star point for d.c. three-wire balancing will also affect the result to a minor degree.

Case 18: Delta-Double Delta Connection.

The flux waves will be practically sinusoidal, but here again a portion of the third harmonic M.M.F. will be provided by each closed delta.

Case 19: Tee Double-Tee Connection.

The double-tee secondaries are balanced as regards fundamental voltages and currents, but are unbalanced from the point of view of the third harmonics. The three points b', c' and n' on one tee are equipotential (see Fig. 24), considering third-harmonic voltages, and

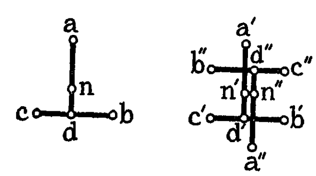

Fig. 24.—Tee double-tee connection.

similarly the three points b'', c'' and n'' on the other tee are equipotential. A third-harmonic voltage exists between a' and n', and an equal one between a'' and n''. Moreover, at the instant that a' is at its maximum positive potential with respect to n', at the same instant n'' is at its maximum positive potential with respect to a''. If the two neutral points n' and n'' are connected together there will be a third-harmonic voltage existing between a' and a'', equal to twice that between a' and n' or a'' and n''. The point a' will now have a harmonic difference of potential from all the other five phase terminals, and, since closed electrical paths exist in all cases, a series of third-harmonic currents are set up. The same state of affairs exists with respect to the point a''. No third-harmonic currents, however, circulate between points b', c', b'' and c''. In order to minimize these harmonic currents the two neutral points are not tied together solidly, but are connected through an inductance. This assists in limiting the unbalanced effects, but the two neutral points both oscillate about earth potential to a certain degree. The potential oscillations are not serious, but the harmonic currents set up may become troublesome on occasion. When the system is earthed this should be done at the middle point of this tie inductance. The flux wave in the transformer core corresponding to $b'c'$ and $b''c''$ will be approximately sinusoidal, but there will be a slight distortion of the flux wave in the other core.

When transforming from two to six phase by means of double Scott connections, the case is practically the same as for the ordinary Scott system described in Case 9.

Case 20: Vee Double-Vee Connection.

This case is practically the same as the plain three-phase vee-vee connection. Small third-harmonic E.M.F.'s are set up in all four secondary windings, and third-harmonic currents flow in the lines connected to a', c', d' and f' (see Fig. 25). The points b' and e' are

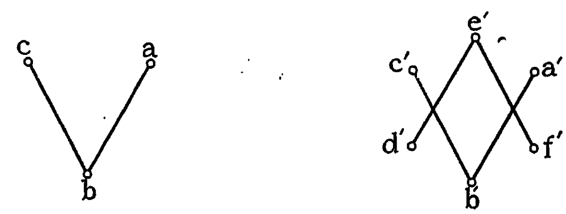

Fig. 25.—Vee double-vee connection.

stable from the third-harmonic point of view. These harmonic currents, together with the corresponding primary ones, tend towards the sinusoidal magnetization of the cores, and so their magnitudes are damped down by the very fact of their own existence.

The authors wish to express their thanks to the Governors of the Polytechnic and the Director of Education for facilities enabling the experimental work to be carried out.

JUSTIFIABLE SMALL POWER PLANTS.

By A. B. MALLINSON, Member.

(*Paper received* 31*st October*, 1924; *read before the* NORTH-WESTERN CENTRE 3*rd February, and before the* SCOTTISH CENTRE 24*th April*, 1925.)

SUMMARY.

The paper generally has been written in the form of an introduction to justify small industrial power plants in areas where a supply is available, and to lead to a discussion on the subject.

Power plants, water, wind, by-product to process steam, from process refuse, household and town refuse, are all discussed, and finally a few comments are made on the small self-contained power plant relative to the super-power station and its network.

Examples are given of capital and operating costs of typical installations in various industries.

The vital importance of simplicity and minimum capital and operating costs to justify such plants is emphasized.

The slogans of "Conservation of our coal," "Super-power stations for cheap power," etc., have been so much in evidence recently, both in the lay Press and in political party speeches, that the general public doubtless feel that such statements are absolutely unanswerable. The object of this paper is to justify the use of the small power plant under suitable conditions.

What can be called a "justifiable small power plant"? The author suggests that a plant is justifiable when it can produce the required power—whether mechanically or electrically used—after allowing for all charges, both operating and capital, more cheaply than it can be purchased from the available outside supply.

Practicable sources of power supply are:—

(1) From water.
(2) From air.
(3) From heating and process steam, as a by-product.
(4) From a process refuse.
(5) From household and town refuse.
(6) From simple, self-contained stations.

(1) THE UTILIZATION OF OUR WATER POWER.

Whilst Great Britain can never, by reason of its geographical formation, produce much power from water, it is somewhat remarkable that in these days of dear coal and talk of the conservation of our coal reserves the water power used to-day, apart from three or four hydro-electric developments, is probably not one quarter of that used, say, 40 to 50 years ago in the days of cheap coal.

The reasons are mainly:—

(*a*) The tendency towards mechanical means, which has necessitated the water-wheel or turbine being augmented by steam power and has led, in many cases, when outside supply has become available, to electric power being installed, superseding both steam and water power.

(*b*) The gradual silting up of the rivers, causing loss of head, particularly in times of flood.

These small falls could be brought into use again if the work were done on the right lines. The author suggests that the layouts should be simple, with automatic or semi-automatic control. With the small powers to be dealt with, there is no margin for unnecessary elaboration in buildings, civil engineering, switchgear, stand-by plant or operation.

With a simple form of control it should be possible to utilize at frequent intervals the small falls along any river, and so avoid trouble with riparian rights, etc. In the United States this subject has recently been brought into prominence by a paper read by Mr. R. J. Wensley on "Present Practice in the Automatic Operation of Hydro-Electric Stations" at the Annual Convention of the American Institute of Electrical Engineers held at Chicago, 23rd–27th June, 1924. Mr. Wensley mentioned these systems as being regularly in use:—

(i) Control by water level, a float switch being employed to start up and stop at predetermined levels.

(ii) Control by system frequency, worked so that as the load comes on and the frequency drops, due to overloading of the running turbines, further turbines at other stations will start up. This is apt to be troublesome if several attempt to switch in at once, and is of no avail if any large station is in parallel on the network.

(iii) Remote control over a pilot wire. This is very effective when stations are not too far apart.

(iv) Supervision control over a telephone circuit. This system, which is now very largely used, enables the distant operator not only to start up, but also to get information in regard to head of water, gate opening, load in kilowatts, load on local feeders, etc.

(v) Control by manual operation of switch in station. This is effective when the size of plant merits a man being in attendance. The man is not expected to be constantly in the station, but to be available when called up by telephone.

(vi) Control by manipulation of the a.c. line. This is occasionally used, the plant in the remote station being started by closing the switch in the man-operated station, an a.c. relay then running the plant up.

(vii) Control by time switch. This can be used where the supply is to works, etc., where the maximum load is known in advance.

In this country the power obtained will generally be of the order of a few hundred down to 20–30 h.p.

There is obviously no possibility of putting such small plants in at a first cost per kilowatt comparable with that of a modern super-power layout, but, once equipped, the cost of operation on automatic or semi-automatic lines would be low.

(2) Power from the Wind.

During recent years several installations have been equipped for obtaining a certain amount of power from the wind. Such plants, provided that the battery is sufficiently large, and that there is, say, an oil-driven emergency set for use during calm periods, will, however, provide a means of obtaining a steady supply of power of only a few horse-power.

(3) Power as a By-product to Heating.

Where steam has to be raised for process or other work apart from power, there is the strongest possible case for the small power plant.

Such conditions occur in paper mills, bleach and dye works, chemical works, sugar and other refineries, public institutions, hotels, laundries, etc.

The cycles of heating and power must, of course, coincide fairly closely, but this will generally be found to be the case; the type of power unit, i.e. back pressure or pass-out, should be decided by a study of these cycles.

The pressures at which the steam is required for the heating process work are approximately:—

		lb./sq. in.
Paper mills	Machine driers	5–20
	Rag and esparto boilers	30–50
Bleach and dye works	Bleaching keirs	25–45
	Stenter heaters	15–40
	Drying cylinders	5–10
	Dye jigs	10–15
Chemical works (various uses)		10–60
Sugar refineries (evaporators, etc.)		10–60
Public institutions (calorifiers)		10–15
Hotels, etc. (kitchens)		5–10
Laundries		10–20

The difference in fuel consumption in raising this steam at, say, 160 or 180 lb./sq. in. in place of the used pressure is very small; for instance, the total heat in steam at 160 lb./sq. in. is only 3 per cent greater than at 20 lb./sq. in.

Actual tests on a large number of installations have shown that even with saturated steam used under favourable conditions the steam loss in passing through the power plant is only ·5–6 per cent. The figure of 10 per cent taken by the author in arriving at the cost per unit is therefore a very liberal one.

In most cases it will be found that the demand for heating steam is more than sufficient to supply all the power requirements of the factory. Under some conditions the margin is such that an appreciable outside supply could be given; a case in point is the sugar refinery at Glebe, recently put into operation with the Greenock Corporation supply.

Where the fluctuations of demand for heating steam are great, e.g. for grass and wood digesters in paper mills, and bleaching keirs and dye houses in finishing works, the introduction of a heat accumulator is desirable. The Ruth accumulator has, during the past few years, been largely adopted on the Continent for this purpose.

Where steam is required for direct heating, no oil must be used—a condition easily fulfilled by using either engines with no cylinder lubrication, or turbines. Superheated steam is generally avoided for heating, but for long pipe runs a little is advantageous to avoid undue pipe losses.

Paper Mills.

The author covered the subject fairly fully in his paper entitled "Electric Driving in the Paper Mill on Heat-Economy Lines." *

The typical case of a British esparto mill boiling 190–200 tons of grass per week may be quoted.

	lb. per hour
Steam for grass-boiling at 45 lb./sq. in.	2 000–10 000
Steam for paper-making at 15 lb./sq. in.	8 000–10 000
Steam for coating at 15 lb./sq. in.	5 000– 8 000
Steam for recovery, breakers, potchers, and general at 20 lb./sq. in.	5 000– 7 000
Total	20 000–35 000

The boiler pressure being 175 lb./sq. in., a pass-out power plant of 600–700 kW to supply the whole of the electric load in the mill is a sound proposition.

Capital cost.

	£
650-kW geared pass-out turbo-generator	7 500
Switchboard extension	250
Wiring	250
Pipework, valves and covering	2 000
Foundations, structural alterations, etc.	1 500
Labour and contingencies	1 000
Total outlay	£12 500

Operating conditions.—132-hour week; 50 weeks per year; 350 kW average load; 2 000 000 units per annum; power plant steam consumption, average extra over heating steam taken at 0·5 lb. per kWh.

Operating cost.

	£
560 tons of coal at 24s.	672
112 tons of ash handled at 3s.	17
Supervision of plant	50
Oil and stores	50
Repairs	100
Insurances	50
Net cost per annum	£939
Net cost per unit, 0·113d.	
Interest and depreciation, 10 per cent on £12 500	1 250
Gross cost per annum	£2 189
Gross cost per unit, 0·263d.	

* *Journal I.E.E.*, 1921, vol. 59, p. 538.

No engine attendants are allowed for, because the man looking after the main engine can supervise this power unit, provided it is put in the same room.

Bleach and Dye Works.

The conditions here are very similar to those obtaining in paper mills, except as regards running hours and load factor. The following data concern a typical works near Manchester.

Capital cost.

	£
Two 150-kW back-pressure sets	2 500
Switchboard (for power plant only)	200
Wiring	100
Pipework and valves and pipe covering ..	2 000
Foundations, structural alterations, crane, etc. ..	1 000
Contingencies	250
Total	£6 050

Operating conditions.—48-hour week, 50 weeks per year; 360 000 units per annum; 10 per cent of engine steam consumption, representing power production (8/1 evaporation) = 265 625 lb. coal (118·5 tons), say 120 tons.

Operating cost.

	£
120 tons of coal at 24s.	144
24 tons ash carted away	4
Stokers	nil
Engine tender	200
Supervision by engineer	50
Oil and stores	40
Repairs	50
Insurances	40
Net cost per annum	£528
Net cost per unit, 0·352d.	
Interest and depreciation, 10 per cent on £6 050	605
Gross cost per annum	£1 133
Gross cost per unit, 0·756d.*	

Mental Institution.

(Rated capacity 1 300 beds.)

Capital cost.

	£
Three 75-kW sets (back-pressure)	2 850
Switchboard	300
Storage battery and booster	1 650
Wiring	150
Pipework, etc.	600
Foundations, structural alterations, crane, etc. ..	1 500
Contingencies	55
Total	£7 700

Operating conditions.—108-hour week, 52 weeks per year; 224 000 units per annum; engine steam, ½ lb. coal per unit, all exhaust being used for heating = 50 tons of coal.

* Public supply:—1·5d. to 0·875d. (various examples).

Operating cost.

	£
50 tons of coal at 24s.	60
10 tons ash handled at 3s.	1·5
Oil and stores	40
Repairs	34
Battery maintenance	260
Insurances	25·5
Extra staff, £3 per week	156
Net cost per annum	£577
Net cost per unit, 0·618d.	
Interest and depreciation, 10 per cent on £7 700	770
Gross cost per annum	£1 347
Gross cost per unit, 1·45d.*	

These three typical cases suffice to show the possibilities of such power plants to generate at an appreciably lower rate than that at which an outside supply can be obtained. They also show the limitations of such plants as regards capital expenditure. The paper mill with its 132-hour week obviously provides the best figure of gross cost per unit; with those plants operating one or two shifts per day, the interest and depreciation item amounts to nearly double the generating cost. It is therefore of vital importance in installing such plants to employ the simplest layouts and concentrate the capital cost as far as possible in the producing equipment; to make a central station in miniature simply means saddling the operating cost with an overwhelming charge.

These figures are fairly self-explanatory, the items requiring explanation being probably the following:—

(*a*) That no capital or operating cost is given for steam-raising plant. The boilers are required for the production of steam for heating, whether the power plant is installed or not, and the stokers have to be there to fire the boilers to raise the steam for heating. The extra 10 per cent of fuel consumed will entail no extra labour, except under exceptional conditions with the steam plant already working up to its limit.

The author's experience is that these steam-raising plants are almost invariably larger than actually required, in order to provide for possible peaks, and are consequently lightly rated.

(*b*) The high cost of pipework. The distribution of low-pressure steam requires a new pipe layout, all pipes being increased to pass the required volume at the lower pressure. In addition, these pipes, in order to secure efficiency, cannot be too well covered.

As power plants on these lines show such low operating costs, why is it that so many works where these conditions exist have taken a public supply? Two typical cases, both with 10-year agreements, for instance are:—

A bleach and dye works with five Lancashire boilers under steam at 120 lb./sq. in. reduced to 15–20 lb./sq. in. for process work, and 100 000 units per month purchased from the supply.

An esparto paper mill using 10 000–12 000 lb. of steam per hour at 180 lb./sq. in., reduced to 50 lb./sq. in.

* In this case an offer for a supply was 3½d. per unit.

for process work, whilst a steady 250 kW is taken from the public supply mains.

The author suggests that the main reasons are :—

(*a*) The possibility that in some cases the boilers were getting old and new boilers would have been required.

(*b*) The capital outlay that would be incurred in installing the plant.

(*c*) The greater reliability of the public supply.

(*d*) The manner in which the case has been put forward by the supply undertaking.

(4) Power from Process Refuse.

The principal sources of process refuse in this country are wood-working establishments of all kinds, tanneries, and blast furnaces, coke ovens, steelworks, etc.

Whilst in the wood-working trades, refuse is utilized for power purposes to a considerable extent, either to raise steam in a more or less efficient manner or in gas-producers, there is a large quantity not effectively dealt with. In a city like Manchester, for example, there are about 100 wood-working establishments—sawmills, builders, joiners, furniture makers, wood box and case makers, etc., producing probably 750–1 000 tons of refuse per week, whilst throughout the country it probably amounts to 100 000 tons or more.

The present outlets for this refuse are :—

(A) As firewood (often a perquisite to the carters).

(B) Sawdust for bedding horses, afterwards being used as manure. Before the European war the bulk of the sawdust produced was disposed of in this manner, but mechanical transport has greatly reduced the quantity. The present price obtained is about 16s. per ton, the purchaser having to provide bags and do the necessary carting.

(C) For kippering at the fishing ports.

(D) Shavings for gas filters and packing; there is a comparatively small demand for this purpose.

(E) For use in firelighters; for this also there is a relatively small demand.

In a typical saw-mill, case and box works cutting up about 55 standards (137·5 tons) per week, the refuse produced during a week averaged per hour :—

	lb.
Cross-cut ends of deals	83
Black board sides	174
Long shooter shavings	11
4-cutter dubbings	90
Sawdust	769
	1 127

This is equivalent to 60 855 lb. per week (say 27 tons or 19·6 per cent of the total). At this works the power required is 100–120 kW.

In existing wood-working shops the layout is in general compactly grouped round the boiler and engine; to introduce a new power plant entails either putting it in a vacant space away from where the refuse is produced —entailing a material increase in the cost of handling the refuse—or shutting down the plant for a month or two while the old plant can be dismantled, structural alterations affected, foundations put in and new plant erected. In consequence the owners usually take a public supply and scrap their engine, and are still faced with the problem of the disposal of the refuse.

In this respect much can be done by the adoption of a more broadminded attitude by the supply undertaking. The author suggests that the ideal method is for works to adopt the electric drive, taking the public supply, and then to scrap the old power plant and install an up-to-date wood-refuse power plant in the central position. Then, when in operation, the public supply could be retained as a stand-by to whatever extent may be agreed upon, the consumer guaranteeing a certain minimum cost per annum.

If, as will often be found to be the case, the power required exceeds that which the refuse can generate, a section of the works could be permanently connected to the outside supply.

On such lines any factory, no matter how cramped its layout, can be modernized and will operate in the most economical manner—economical not only from the user's point of view but also from that of the national interests.

Such power plants can be either (1) steam with suitable combustion chambers, or (2) gas with suction producers, the former requiring from 4 to $4\frac{1}{2}$ lb. of refuse per b.h.p.-hour, and the latter from $2\frac{1}{2}$ to $3\frac{1}{2}$ lb.

Typical City Saw-mill Installation.

(Steam plant fired with refuse in an underground step grate, locomotive-type tubular boiler.)

Capital cost.

	£
130–150 h.p. locomobile steam plant	1 800
Dynamo belt drive	400
Foundations	350
Switchboard	200
Wiring	100
Pipework and sundries	200
Structural alterations	300
Contingencies	250
Total	£3 600

Whilst gas is the more economical on paper, there are other factors, such as the provision of steam for seasoning, heating, etc., and the class of refuse produced, which must be taken into consideration.

Operating conditions.—48-hour week, 50 weeks per year; town's water to boiler; 168 000 units generated per annum.

Operating cost.

	£
Labour: Fireman	175
Labour: Engine tender	195
Water	15
Oil and Stores	35
Insurance	15
Maintenance	50
Net cost per annum	£485
Net cost per unit, 0·692d.	
Interest and depreciation, 10 per cent on £3 600	360
Gross cost per annum	£845
Gross cost per unit, 1·21d.	

A public supply is available at 1·25d. per unit. If used, however, material charges for handling and disposal of the refuse must be added. In addition, the steam provided for canteen cooking, office and shop heating is not taken into account.

Bobbin Works.

(Steam plant fired with wood refuse, underground step grate and locomotive-type tubular boiler.)

Capital cost.

	£
420–515 h.p. locomobile	4 500
Direct-coupled alternator	2 500
Switchboard	400
Wiring	200
Pipework, etc.	150
Foundations	500
Structural alterations in old engine house	1 000
Contingencies	550
Total	£9 800

Operating conditions.—275 kW steady average load, 660 000 units per annum.

Operating cost.

	£
Engine tender	200
Fireman	175
Town's water	35
Oil and stores	75

Interest and depreciation, 10 per cent on £3 800	380
Gross cost per annum	£830
Gross cost per unit, 1·19d.	

Plants of this character can very often be installed as a direct drive. This would reduce the capital cost by, say, £500.

Refuse-gas plants are now well past the experimental stage. They are adaptable to a wide range of waste products available in this country, from wood refuse of all kinds to tannery refuse, barks, etc., and even stable manure.

Surplus Gas: Blast-furnaces, Coke Ovens, Etc.

The utilization of surplus gas for power purposes is now practically universal. Such plants have been highly developed and in some areas, such as the North-East Coast, the power plants so operated feed into the public supply networks. Until a few years ago, plants were generally gas-engine driven, but the later developments have in the main been by steam turbines from gas-fired boilers.

(5) Household and Town Refuse.

The refuse destructor has long ago proved the practicability of power generation from town refuse. Such plants may be small, but all tend to the common end, i.e. national economy, and as such should receive every encouragement. There are undoubted difficulties in their extended adoption, such as small capacity, cost of staff, dusty surroundings, etc. The author suggests that the financial results obtained with this type of plant could often be improved if steam were sold for heating in addition to the production of power. The difficulties caused by a fluctuation of the calorific value of refuse, etc., would be overcome by the installation of stand-by or emergency oil engines.

(6) Simple, Self-contained Power Stations.

Whilst primarily this paper has been written to deal with the small power station fed with refuse, or steam as a by-product, there is, in the author's opinion, in many places at least a strongly debatable case to be made out for the self-contained small station. The capital outlay for super-power stations, long transmission lines, substations and the like, is very large, and this must introduce a heavy charge on the cost per unit in scattered areas with a low load factor.

In a typical example with a steam-driven station of 2 500 h.p. capacity, the total generating cost, including

rates and taxes, is 1·0d. per unit, part of the plant being over 20 years old.

With the highly efficient steam or oil prime movers available to-day, these small stations show very favourable results. The tables of electric supply undertakings published with the *Electrical Times* show many small stations with total works costs of 2d. and over per unit, but the author suggests that it is not fair to compare the modern super-power station operating costs with these, which are generally for more or less old and inefficient plants. If a new super-power station and its network were to be compared with new, small power plants of the most efficient type, there would at least be a case for argument. The author hopes that this most debatable part of the subject of power generation and distribution will be dealt with in the discussion.

Conclusions.

The predominant factor in all considerations of small power plants is capital cost. The figures quoted of different installations which have been quoted emphasize this clearly. There is no room for "frills"—miniature central stations and the like—and nothing but bare necessities should be installed. In the same way the operating costs must be kept down, especially on these small stations having low load factors.

Discussion before the North-Western Centre, at Manchester, 3 February, 1925.

Mr. S. J. Watson: With many of the author's statements I am in cordial agreement. There are undoubtedly many cases in this country where steam or burnable material is wasted which might otherwise be used with great advantage by the owners of the plant. I think that his remarks particularly apply to such industries as the paper-making and wood-working trades. In a number of instances wood-working machinery is entirely driven by gas produced from the waste wood which is torn off in trimming, etc. Under such conditions it is absolutely impossible for any supply undertaking to compete. It is utilizing, under extremely efficient conditions, what would otherwise be absolutely waste material. With many of the estimates put forward by the author I do not agree. In these estimates he shows the amount of power used, and the annual output obtained, but he does not attempt to charge anything at all for the capital expenditure on buildings or boilers, nor, in the majority of cases, for the wages of operators. I am aware that in the course of the paper he excuses himself by reason of the fact that much of the plant would be installed in any case, but it might equally be said that the plant was originally installed for power purposes and was subsequently used for heating purposes. I suggest quite seriously that if he is going to make such comparisons he ought at least to take into account a portion of the capital charges and working expenses which are justly attributed to the work done by the plant. If he does that, the final figures of cost per unit will be much altered. Another point to which I take exception is that the author charges a very small amount for repairs. It is quite true that he takes 10 per cent for interest and depreciation, but I find that in many cases he has included storage batteries, and many of us know to our cost what the maintenance of a storage battery entails. He has only included something less that 1 per cent, and I venture to suggest that he ought to make a very much larger allowance. One of the reasons why manufacturers prefer to take a supply from a public source is that the responsibility for generating their own supplies is a constant source of worry and trouble to them. Dealing with the subject from a rather broader aspect, supply undertakings are constantly experiencing the case of manufacturers who have put in their own plant and find it to their advantage later on to discard it and use the public supply. Such changes apply not only to what I may call "straight" power industrial undertakings but also to the particular types of industry which the author singles out to show that it is an advantage to generate their own power, such as dye works, for instance. Numbers of such works utilize the public supply. Many of them deliberately discard their own plant and the problematical savings which they may effect by its use and come upon the public supply mains, thus indicating clearly that they consider that there is an advantage in so doing. Apart from certain very special cases, the costs per unit given by the author are not as low as those of many power supply undertakings in the country for similar supplies. As an instance, two or three years ago I was interested in a very large paper mill which required some 200 or 300 additional horse-power, equal to a consumption of about 2 million units a year. I negotiated with the local supply undertaking, and the lowest price that they were prepared to quote for the supply was 1¼d. a unit. Such a price was, of course, quite unreasonable. At that time I was associated with an undertaking which was supplying energy at less than 0·50d. per unit. The reason why greater progress is not made is very often that the supply undertaking does not take the long view in regard to this matter. I think, however, that all over the South-East Lancashire district the prices at which power is supplied to-day do not vary very much from most of the figures given by the author. The author includes no item for local rates. No concern can spend £12 500 in increasing the value of their property without the knowledge (sooner or later) of the local assessors, and rates and taxes to-day represent no small proportion of the cost which the supply undertaking has to bear. One of the most important reasons why the combined use of steam for power and for process work does not make greater progress is that in many cases the time when the maximum amount of steam is required for process-work does not coincide with the time when the maximum amount of steam is required for power purposes. In such cases it is impossible to get the best results out of the combination. Another point is that most of the figures given in the paper are for single private plants, whereas in connection with supply undertakings considerable expense is incurred in providing spare plant so that an uninterrupted supply

can be maintained. The time lost to manufacturers through interruptions of the public supply is very much smaller than in cases where the plant is installed on the premises. There again by taking a public supply the manufacturer stands to gain. I entirely agree with the author that we in this country have not made as much use as we should have done of the large aggregate amount of small power available from our streams. In this district there are a number of cases where the river water, in passing over the weirs, is at a head of from 6 to 8 ft. My undertaking keeps records of the flow which comes through Salford and we know that it varies from about 2 million gallons up to 30 or 40 million gallons per hour. This represents a very considerable amount of power. I agree with the author that in the future it should be made compulsory to take advantage of such natural power supplies where they exist. I have been associated with refuse destructor plants on one or two occasions, and the most satisfactory one of which I heard was in a town in South Wales where the value of the ashes was high, inasmuch as free coal was supplied to the miners. This particular undertaking was burning the ashes in a destructor and obtaining sufficient steam to generate between 2 and 3 million units a year, which were sold to a power undertaking. Many others, owing to the nature of the refuse, were hardly producing sufficient steam to run their forced-draught fans, and in some cases they even had to supplement the refuse by means of coal in order to maintain the plant in operation.

Mr. J. Frith: I quite agree with the author that the supply undertaking should, and in most cases will, help a firm to install a power plant of its own. I have even known cases where the supply undertaking has not only provided a stand-by supply but has bought the surplus energy. I also agree that in many cases small self-contained generating plants can be put in and show a good financial comparison with purchased power. They can be of a type which requires very little attention, are cheap to maintain and have none of several very large items of expense which the supply undertaking has. It is certainly surprising, as the author says, that so little of the water power of English rivers is used. I have been connected with one or two water-power projects and I have been equally surprised to find the number of people who have water rights on our rivers. The vested interests are very difficult to override, but Parliament might possibly take steps to dispossess the owners. The author does not mention waste-heat plants; just lately I have been concerned with several boiler plants making large quantities of steam from otherwise absolutely waste heat.

Mr. A. E. Clarke: I think that we are rather apt to consider in these days of super-stations that a public supply is the cheapest and best source of power, whereas in certain circumstances this idea may prove fallacious. As the author suggests, there are undoubtedly many applications for which a strong case may be made out for private power plants. It is necessary to proceed most cautiously, however, because in some cases it is fairly easy to prove on paper that private supply would be the cheaper, whereas in practice the reverse is proved to be the case, and vice versa. In this neighbourhood there is a flour mill which was erected some time previous to 1914, a replica of a steam-driven mill the property of the same company. The directors decided to install electric drive and to purchase their supply from the local authority. At the time a comparison on paper of the costs of steam and electric driving showed a decided gain in favour of steam, but they believed that as the use of electricity extended, so costs would come down until no difference existed between the expenses of the two methods. At first the experiment proved costly, but since then for a variety of reasons the output of the mill has been nearly doubled, and the cost of power per sack of flour reduced until it is lower than that of similar mills running at present under steam drive. So satisfied are the directors with their experience that they have under consideration the complete change from steam to electric drive in other mills. They recently purchased a mill which up to the time it was bought was driven by gas-producer plant, and after a short experience of this method of drive they have scrapped the gas engines and producer and are taking a supply from the local supply undertaking. Here was a case in which it was demonstrable on paper that with a load factor of 65 per cent private supply would be the cheaper, whereas the opposite has been proved in practice. I shall now give an illustration to show the other side of the question. A small plant of 100 h.p. produced a certain article from wood balks in which the operating conditions were difficult on account of the heavy intermittent loads. The load factor was only 16 per cent, and the net rate per unit high. Here the power charges constituted a large proportion of the manufacturing costs, a proportion so high as to cut out all profit at the prices obtainable. The consumer was rapidly becoming insolvent and, after discussion with a well-known manufacturer of oil engines, decided, under very generous terms on the part of the engine makers, to install a semi-Diesel engine. This was done about 18 months ago, and the result is that the power costs are now roughly one-third of the supply undertaking's charge. Now mark the importance of power supply in its incidence on manufacturing costs. This consumer after the installation of the engine was, in virtue of his lower manufacturing costs, able to cut his prices and more business resulted until he was able to run his plant 100 hours per week. This of course resulted in a further reduction in his costs, by means of which he has been able to keep his plant in full operation, has paid for his engine and is now making quite handsome profits. I am thoroughly in agreement with the author's views as to supply in special cases and could quote several examples of saw-mills, wood-working shops and works using steam in the production of various manufactured articles, all obtaining their power as a by-product, in which the supply undertaking's price is cut by a large percentage. The true conception of the power problem appears to me to be that each case must be considered on its merits, and that only after meticulous investigation and with the greatest discretion must a decision be come to as to which method is the more advantageous.

Mr. G. F. Sills: It should be remembered that the author is making out a case for a few trades only, because in the ordinary factory working 8 hours a day, with little

or no low-pressure steam required for process work or heating, it is normally impossible to generate any more cheaply than to buy power from a moderately large supply undertaking. The author makes no allowance for management costs; these should be taken into account. The great advantage in buying power consists in the reserve plant available in public generating stations; it is very unusual for a private plant to have any stand-by. In the normal factory any small saving made in generating its own power would be cancelled if a stand-by were installed. Many factories would rather pay a little more for bought power to save the extra capital outlay in purchasing their own generating plant. A good arrangement where low-pressure process steam is required is to put in a steam set to use all the high-pressure steam for generating power, then to send the exhaust or pass-out steam to the process work, etc., electric power that cannot be supplied by this steam plant being purchased from an outside source. A case came to my notice only a few days ago, where a few thousand pounds of low-pressure steam were required for process work on a 24 hours' load. The factory manager proposed to install a 160-lb. boiler and a steam set to use all the high-pressure steam available, to use the low-pressure steam at 10–15 lb./sq. in., and to buy the remainder of the electric power required. It will be realized that the boiler had to be used in any case, and about half a million units could be generated a year for the capital cost of the steam set plus about 10 per cent on the cost of the fuel—representing the extra cost of first using the high-pressure steam in the manner indicated. The supply undertaking had sent in the printed agreement which stipulated that all electric power used should come from their mains. Surely it is in everyone's interest to obtain the maximum benefit from every pound of coal, and I would suggest that it is against the interests of any public supply undertaking to make such a suggestion in these circumstances. The supply undertaking actually argued that the buyer should not make use of his steam as explained above. When they were told that if they still insisted the factory would generate all its own power they gave way. The author gives some figures referring to costs of insurance. Is this why the repair charges in the tables appear to be on the low side? On a plant where process steam is required and a small generating set is used, it should be possible to have one man to look after the boiler and the set. I understand that in one case it was doubtful if the local unions would agree to one man doing this work, and it seems more than absurd if this is so, as it means an unnecessary addition of £4 per week per shift to the generating costs. Referring to the question of water supply, I believe that the Electricity Commissioners have power to adjudicate in these matters. In connection with power-supply charges, manufacturing firms get out a good many schemes for private generating plants for factories already buying power from a public source. It is probable that these schemes are often only a means of forcing the supply authority to reduce the cost of power. Referring to the author's remarks about blast furnaces, is it not a fact that most of the large steelworks in this country use the blast-furnace gases in gas-engine generating sets, and do not normally burn the gases under boilers?

Mr. W. Dundas: I believe that the principal factor which inspired the author to write his paper was that of fuel economy, and he has indicated a direction in which to look for improvements. The problem depends upon a number of conditions and circumstances, e.g. relative demands and capacity of boiler and power plant, coincidence of the demand for process steam and power load, stand-by plant, capital and labour costs, etc. I think that the author has rather underestimated his labour charges in the examples quoted. I have looked into the examples given in the paper, and in the case of the paper mill the whole of the power should be obtained from the process steam, that is, if the two supplies can co-operate, but evidently such is not the case as an additional 560 tons of coal is required to balance the power load, which corresponds to approximately 0·5 lb. per kWh and not 5·0 lb. as stated in the paper. Generally speaking, it is possible to effect a gain from 10 to 13 per cent on the total steam required. The two cases referred to on page 898 are instances where the combined plant is justifiable and every attempt should be made to conserve fuel, but that cannot be done at the expense of the electricity supply undertaking, which cannot reasonably be expected to give a stand-by supply at a very low rate. The minimum charge must cover at least the fixed charges on the capital cost involved in furnishing the supply.

Mr. W. J. Medlyn: I think that the author goes too far when he assumes that certain costs of upkeep and running of the electrical plant can be ignored, simply because a staff has to be provided in any case for the running of the steam plant. At the same time the elimination of actual waste is, of course, a very definite gain where this is found practicable. Take the case mentioned towards the end of page 897, for example. It is shown that 560 tons of coal are required for the electrical plant—just over 10 tons per week—but nothing is allowed for the labour of handling this nor for the extra cost of storage. Of course it may be a fact, as suggested by the author, that there is a surplus of labour employed on the steam plant, but that does not appear to be a sufficient reason for employing the surplus in other ways without a proper subdivision of the charges to be in agreement with the actual facts. Even if there is no way of economically using the surplus at the moment in any particular case, the manufacturing conditions vary from year to year. Then, again, it appears to be assumed in the paper that this valuable plant will practically run itself without any trained electrical staff, but with unskilled and untrained attendants in charge of the electrical plant I should expect costly and inconvenient breakdowns which might have a serious effect on the output of the works. Also I should not like to risk running an electrical plant without some supervision by a trained and competent electrical engineer. In those cases where electrical machinery is already installed these points are, of course, subject to modification, but they are not very definitely dealt with by the author. At the end of page 899 a case is quoted where the cost of generation is estimated at 1·21d. per unit, and at the beginning of the next page a public supply is stated to

be available at 1·25d. per unit. Apart from the criticisms already referred to, I suggest that with such a small margin this is clearly a case where the risks of the special installation should not be incurred. The cost of handling wood refuse is referred to, but in another part of the paper there is stated to be a market for saw-mill waste. It would be interesting to know what life of plant has been allowed for in the calculations. Until within comparatively recent years the Post Office had a number of small generating stations of capacities ranging from about 150 kW to 500 kW in London and the principal provincial towns. These installations were associated with heating systems and other services, and many of the economical side-lines advocated by the author were in operation. Owing to the importance of public requirements it was necessary to keep a good reserve of plant to ensure continuity of service, and the load factor was therefore poor. Of course, in manufacturing works, continuity of service is an important factor also, and a breakdown might result in serious loss. When most of our generating stations were erected (about 25 years ago) the possibility of a breakdown of the municipal supply was greater, and the comparative cost of energy much higher, than at the present time, and it has since proved to be an economical proposition to close the stations and take supplies in bulk from the supply undertakings. The quantity of energy taken, and the good day load, were factors which had a bearing on the question of the terms of supply. The valuable space rendered spare due to the withdrawal of the generating plant was also a matter of some importance. It is therefore evident that the case for steam-driven generating stations of about the capacities mentioned by the author cannot be supported so far as our experience goes.

Mr. G. A. Juhlin: I do not think it is possible to generalize on the question of individual power plants versus large central stations. Each case has to be considered on its merits because the importance of the various factors which determine whether it will be cheaper to purchase power than to install a generating plant must necessarily differ in each case. It must not be overlooked that there are some factors which cannot be easily assessed in monetary value, such as freedom from trouble associated with the running of a power plant, which fall on the shoulders of the supply undertaking when power is purchased. The author refers to the fact that more water power was utilized 40 to 50 years ago than to-day. I do not think this can be taken as any indication that there is less appreciation of economical considerations to-day than 50 years ago. The shutting down of the small individual water-driven mills is simply due to the growth of our large industrial centres, with better facilities for labour, transport, etc., which has made it possible to deliver the goods to the consumer at a lower price than could be done from the mills situated at points where water power was available. With regard to the small automatically-operated hydro-electric power plants in the United States to which reference is made in the paper, I believe that these are situated in districts where the cost of coal is very high, which makes it economically possible to pay the high capital charges involved in some of these hydro-electric stations and still compete with steam plants. Looking at this question from a domestic consumer's point of view, one cannot help feeling that if the whole coal cost were eliminated it would not materially affect the cost of lighting and power for household purposes, because the cost of the fuel is but a small fraction of the total cost. In connection with the burning of refuse from wood-working factories, I have seen several mills in Sweden where this was done and it is not uncommon to see coasting steamers burning the ends cut off planks and logs.

Mr. T. E. Herbert: The author makes one very good point, viz. that the correct thing to do in all these cases is to see that our coal supply is conserved, and he would like to see it made a penal offence for coal to be needlessly used. If it is a fact that any public supply undertaking uses its position to compel a man to take the whole of his supply from the public mains when he can get energy in another way by eliminating waste, such procedure appears to be wrong in principle. The value of having a perfectly reliable supply is very considerable, but there are cases where a small stand-by plant is absolutely essential. For example, in the case of a telephone exchange there should always be some method of getting the necessary electrical energy if something goes seriously wrong. Fortunately, the use of secondary batteries means that there are several hours available in which to make the necessary arrangements. One hopes that no serious disaster to the main power stations will happen, but arrangements have necessarily been made to avert such an emergency.

Mr. E. Rothwell: I thoroughly agree with the author's remarks regarding public institutions. I do not see how it is possible for a public supply to compete with a properly designed institutional central heating and power plant. When one considers that institutional requirements comprise heating, lighting and power continuously the whole year, night and day, it enables the coal to be used to provide all the necessary services with the utmost economy. The institution, for instance, in which I am interested has spent £56 000 in 7 years for fuel and gas, and it will be recognized that opportunities do arise to deal economically with the fuel question. The essential demand is heat and this has to be met by some means, either by separate domestic boilers or a complete central heating arrangement: also there are demands for steam for laundry purposes, hot water supplies, cooking, etc., and electrical energy simply becomes a by-product when exhaust steam can be utilized for most of the above requirements. I have devoted much study to this question and I certainly think that the title of the paper is very appropriate, particularly when one thinks for a moment of the enormous amount of heat thrown away daily in condensing plants. I know quite well that it is unavoidable in the majority of cases, but I do consider that every effort should be made by engineers to obtain the utmost from the coal that has to be burnt. This is not so in many cases. I am quite satisfied that where exhaust steam can be created by the generation of electrical energy and completely absorbed for useful heating services one can with confidence extend the application of electrical energy for all sorts of uses

and feel that every current-consuming device is utilizing the coal to the best advantage. It must also be remembered, as the author points out, that in every case boiler plant is necessary, even if a public supply is purchased, and when their maintenance cost is considered this makes the case for private plants beyond question, because under either arrangement the current-consuming appliances require a staff for their maintenance, and this staff is ample to supervise the generators.

Mr. J. Aylmer: The policy of the Electricity Commissioners is the rule which we should all follow, but there are exceptions to every rule, and we ought not to lose sight of this. As an electrical man I have felt very strongly in the past that it is one's duty to endorse the policy of the Commissioners, but when one comes across cases like those which have been mentioned, as an engineer one has to face facts. As a previous speaker has said, each case has to be considered on its merits, and these special cases which the author has put before us are indubitable. I consider he has been very fair: he has not given us, by any means, all the cases that he might have done, and I should have liked to hear the opinion of some of the engineers of the bigger combines in Manchester which run their own stations. Some concerns run their own plant, in spite of the objections mentioned by various speakers. I have in mind a case of a mill in the Manchester area which uses no steam at all for process work, but which has just put in a new set to replace an old one. From experience gained during the past 18 years they found that they could generate more cheaply themselves although using no process steam. Mr. Watson referred to a case where a supply undertaking quoted 1¼d. a unit for a supply. It would be interesting to know whether that was a small outlying station where the overhead charges for transmission and so on were heavy and had to be added on.

Mr. A. Tustin: In common with other speakers I believe that the method of making comparative estimates which the author has adopted is the correct one, in so far as he does not include in his cost of production of current any allowance for items such as boilers, which, though they are necessary for the production of electrical power, would have to be installed in any case, whether electrical power were generated or not. This question comes up in discussions from time to time and is never very satisfactorily dealt with. It seems to me that the right way to decide how a comparative estimate should be made up is to be clear in our minds, first of all, for what purpose the estimate is to be used. The right way to make up the estimate is the way which best fulfils its particular purpose. Any particular method may sometimes be right and sometimes wrong. Such an estimate as the one in the paper may be made by a private individual who is making up an estimate of the costs of various alternative possibilities with a view to enlarging his profit. What he wishes to know is, which of the two possible alternatives will actually, in point of fact, give him the biggest excess of income over expenditure in the future. It seems to me perfectly clear that from that point of view the author's method is the correct one, because, if one were to adopt the alternative method and distribute those costs "justly" between the two uses of the boiler plant, then the individual consumer concerned might actually adopt, on the basis of that estimate, a line of policy which will in fact give him less profit than he could otherwise obtain. That is not the kind of thing that private enterprise usually has in view. Secondly, an estimate may be made up from the point of view of public policy. There again it seems to me there can be no doubt that to leave out of the estimate all charges which are not *additional* charges caused by the development of the electricity supply is the right policy. In the particular example before us the omission of all charge for boiler plant in making up the estimate for the cost of production of power from process steam is giving the real economy of that proposal a chance to appear in the comparative figures. If such an estimate determines a user to install back-pressure plant, then it has been the means of securing the adoption of a policy which really does something to aid the conservation of public resources instead of leading to the development of two entirely separate sets of boiler plant where one would suffice. Thus, in spite of the criticisms which have been made of the author's system of making comparative estimates, which includes no charge for items of plant which would have to be installed in any case, we must conclude that his method is the right one. It is right for the private individual because it enables him to choose the alternative which really will make his profit a maximum, and it is also right from the social point of view because it causes the choice to be made which will give the maximum real economy of the nation's resources.

Mr. W. A. Christianson: I agree with previous speakers that each case should be considered on its merits, but I feel that where steam is required for process work or heating, a case can invariably be made out for an independent power plant, and frequently also where no process steam is required. Apart from the process steam case, air- and water-heating is a general requirement of every works and building of a public nature and offers a suitable field for an independent plant. As the factors affecting power and steam production costs have been more thoroughly appreciated, and the utilization of pass-out steam or exhaust from prime movers, coupled with economies from condensing, have been developed, the independent plant has fully met the competition of the public supply. This is evidenced by the amount of business being done by manufacturers of prime movers of all types and sizes which come within the range of "small power plants." As the size of installation increases, so does the case for the independent plant become stronger. Like the author, I have wondered why some works using process steam take a public supply, and I would suggest that a lack of appreciation of the possibilities of combining power and heating is the cause in some cases. I do not, however, agree as a general statement with the greater reliability of a public supply. The converse is just as likely to be the case. I heard of a works generating their own power—of quite a large amount—by steam engines and turbines working condensing and also using a large amount of heating steam direct from the boilers. Ultimately, however, the wastefulness of this arrangement was realized, and the power and heating com-

bined, with considerable resulting economy. I know also of two industrial concerns to-day each taking power from a large local undertaking whilst making their own steam for process work. They are now proposing to install their own generating plant to provide for their combined power and heating requirements. In addition to the economy to be gained, one of these concerns considers it a matter of importance to have its own power plant so as to have control in its own hands and avoid being " shut down " through a possible strike affecting the public supply over which it has no control. I believe that there are still a large number of plants in a similar position to the above in which a combination of power and heating requirements would be very advantageous. In cases where an independent plant is installed—and especially when this consists of one unit only—the public supply can with advantage be combined in the scheme to provide a complete or partial stand-by and also to meet the small night or week-end requirements which would not justify the running of the plant. I am in general agreement with the author, but I think that the figures of costs deserve further examination. Though the comments of previous speakers have been in the direction of inflating the figures quoted I should like to reduce one of these at least. The author gives the cost of a 650-kW geared pass-out turbo-generator set as £7 500. I believe that a plant of this character and size could be purchased and installed at the present day for £4 000 at the outside, or £5 000 including a condensing plant.

Mr. H. C. Crews: Small private plants relieve supply companies of their peak load, and I have in many cases been able to make agreements for an alternative supply where we have undertaken to avoid the peak load, unless advance arrangements were made with the supply undertaking on the telephone. This plan has worked very well. We have always been willing to take a sufficient number of units annually to make it a paying proposition for the supply undertaking. Where accumulators have worn out, instead of replating them we have in several cases connected the public supply. It is an advantage in many cases. Sometimes it is required to clean out the boilers, etc., and by arrangement the supply undertaking will take the whole load if they are in a position to supply. The author has referred to the way in which people are approached by supply undertakings. I should like to give an example of what occurs; it is very unfortunate that this is done occasionally. A prospective consumer is told that he can be supplied at, say, 0·3d. or 0·4d. plus a *small* fixed sum. At first that business man does not realize how this latter works out, but on investigation it is found that the fixed sum may perhaps be 0·9d., and that there are coal clauses which may mean an additional 0·1d. or 0·2d. When he has finally gone into the whole thing this business man is annoyed to find that the cost may work out to, say, 1·4d. per unit over all; and he thinks he has been deceived. It does the supply undertaking no good and sometimes it is too late to reconsider the matter. A great many public supply connections have been turned down for that reason; the business man thinks he has been deceived. Of course the crux of the whole question of private plant versus public supply is that every case must be considered on its merits. There are plenty of cases where a private plant does pay and pay very well. I am responsible for a number of supplies for public schools all over the country, and the majority have their own private plant. In four cases I have in mind, three have their own generating plant in duplicate. The fourth school, when their agreement ends with the supply undertaking, are going to install their own plant, because they can easily cover all capital costs on the same in five years' running, based on actual results of three similar cases. I have replaced private plants by public supply more often than the reverse, but in many cases private plants have been supplied and, taking into account every figure, have shown a saving. Local conditions decide the question entirely.

Mr. H. C. Lamb: As some speakers have already said, very often the question of private plant or public supply largely depends on the degree of importance which the power user attaches to reliability. The author gives two examples where people who might have used their own private plant have preferred to come on a public supply system. A hundred instances in Manchester could be given where chemical works, dyeing and finishing works, saw mills, paper mills, and so on, have preferred to come on the public supply, no doubt for sound reasons. It has been stated in the discussion that some supply undertakings refuse to give a supply of power to a consumer unless that consumer guarantees to take the whole of his power from them. There is certainly some misunderstanding here, and I do not think that any supply undertaking would attempt to make a rule of this kind Possibly there are special cases where it would be unprofitable to make an expensive extension to mains unless a definite load were guaranteed, and it is some such case, I think, which has given rise to the misunderstanding. There are many examples in Manchester of works driven partly by consumers' own plant, and partly from the Corporation's mains. It is not easy to check the author's figures. He speaks as an expert of matters with which he is familiar. Comment has been made on the small sum allowed in the paper for repairs, and it was suggested that the payments for insurance also covered repairs, but it is safe to say that no insurance company would insure and also carry out repairs for the trifling annual sum of £15. With regard to the operating figures on page 897, I notice that in the first case the coal is given as 560 tons, and the ash as 112 tons, that is to say, the ash removed is 20 per cent of the coal consumed. A coal with 20 per cent of ash, and the usual amount of moisture, will have a calorific value, as fired, of 10 500 B.Th.U. Allowing 1 050 B.Th.U. per lb. of steam, then to get 8 lb. of steam per lb. of coal, as the author does, means that these boiler houses are working, week in and week out, at an average efficiency of 80 per cent. We know from Mr. Brownlie's figures* that he tested 400 private plants and found that they had an average efficiency of 58 per cent. If anything like this obtained in the cases cited in the paper, the operating figures for coal (the principal cost) would have been considerably higher. The part of the paper dealing with process refuse is extremely

* See *Journal I.E.E.*, 1924, vol. 62, p. 385.

interesting. The author has given his views on the proper function of supply undertakings, whose duty apparently it is to give a temporary supply to suit the convenience of any consumer who wishes to take out his old plant and put in new. The public supply will then not be wanted again until the next emergency occurs. Of course a stand-by supply cannot be given without proper payment. The Electricity (Supply) Act of 1922 recognized this and absolved all supply undertakings from the obligation of giving a stand-by supply without a payment which would cover the fixed charges; and any supply undertaking will act as a stand-by on these terms. The author has given a good testimonial to the sales departments of the supply undertakings, but I do not know that they are really entitled to credit for any special wiliness, because it seems to me that a saw-mill owner's ordinary business keenness would put rather a different complexion upon the case. In this instance the author gives a figure of £845 as the annual cost of power generation by the saw-mill plant, but the balance sheet is not complete because he has not added the revenue which would have been obtained from the sale of the refuse, supposing it had not been consumed. He said that sawdust could be sold at 16s. per ton, and the works in question are making about 800 tons a year; so the sawdust alone would be worth something like £700 a year. If that be added to the £845, the total cost is far in excess of what it would have been if power had been obtained from a public supply. The author concludes by stating that a good case can be made out for the small plant. He says, "the capital outlay for super-power stations, long transmission lines, substations and the like, is very large, and this must introduce a heavy charge on to the cost per unit in scattered areas with a low load factor." It is quite true that the cost of super-power stations is "very large," but the important point is that the cost per kW for a large plant is far and away less than the cost per kW for a small plant. That is seen from the figures given in the paper. The cost per kW for a 25 000-kW turbo-alternator of the most expensive type, using high-pressure steam and high vacuum, is only about one quarter that of the small plants referred to in the paper. The fact is that a very large public station, with its high-tension mains and distributing stations can be put down at a lower capital cost than the small self-contained station. I feel strongly that the author is advocating a retrograde step when he suggests that there should be more small power stations. It does not seem desirable that we should have a forest of chimneys in our industrial towns, making it all the more difficult to tackle the smoke nuisance. Nor is it in the public interest to multiply small private power stations which must almost inevitably be much less efficient than the large station where the whole business of the operators is power production.

Mr. E. E. Baker (*communicated*): I should like to supplement the instances which the author has cited with results from other manufacturing firms who have been working for a considerable time with their own plant on a combined power and heating system. An undertaking in this country, which is probably one of the largest, consists of 8 000 b.h.p. in back-pressure steam dynamos at its various branches, the largest units being 500 kW. This is an undertaking which has been built up by degrees and was started many years ago, the programme being gradually to convert the works to a combined system, power and heat for the process work being generated in the same banks of boilers. There has been no difficulty in establishing a steam balance, the boiler plant has been reduced by as much as 40 per cent in some instances and the bulk of the electric supply, which was previously taken from an outside source, is now generated on the premises. The plant is all arranged on the unit system and a great deal of consideration has been given to arrive at the most simple and reliable plant for the purpose, with the result that a continuity of supply has been maintained with practically no stand-by plant and consequently with low capital expenditure. The results in fuel saving, cost per unit and improved process-steam distribution have more than justified the undertaking, which is still in the process of further development. Other instances show equally good results. A paper works is generating power at a cost lower than that at which a supply from an outside source could be obtained. A works manufacturing a speciality saved £1 200 in the first six months. A dye works, an institution and a public school are other instances taken at random where savings of £700, £2 000 and £200 respectively have resulted. Comparing the cost of production with that for any other scheme, the reason for the saving is so obvious that it is difficult to conceive any other result. In instances where steam balance presents any difficulty there should be a favourable opportunity for working in conjunction with a public supply, if one is available. Works will naturally install their own plant up to the extent of their demand for process steam, excess power being drawn from the public supply, the arrangement being automatic and controlled by the process-steam demand. The advantage of this system is that condensing, the weak link in the chain, is only employed in the large sets of public supply undertakings, where the sets can be run on good load factors with the minimum fuel consumption. At the present time many works install pass-out plant, which is another way of dealing with the steam balance question, though such firms would gladly buy any power in excess of that obtainable with their steam-heating demand if they could obtain it at a price which would pay them better than installing the pass-out plant. In connection with a pass-out plant it should be borne in mind that if the load factor on the low-pressure end and likewise the condensing plant is a poor one it involves a heavy capital expenditure, and a plant may not run with quite the best economy on purely condensing conditions when not passing out. But if, as Mr. Sills points out, the public supply undertaking is going to put all kinds of restrictions on consumers who have sound fuel-saving schemes, the advantages of such combinations will be lost and both the public supply undertaking and the consumer will be the sufferers, to say nothing of national interests as regards fuel economy. There is, of course, nothing new in the back-pressure engine; it has been working most economically on these lines for years, and the reason why it is now so prominent is the cost of fuel and

labour. Manufacturers want more power from fewer boilers and there is no other way of getting it, and as during the last two years one of the leading high-speed forced-lubrication engine manufacturers has turned out 130 engines operating on this system, totalling some 25 070 b.h.p., the public are obviously realizing the advantages of the proposals which the author has put before us.

Mr. R. A. Baldwin (*communicated*): The author has very rightly drawn attention to the publicity which is apt to lead the uninformed to suppose erroneously that it is from super-power stations that we are to obtain the cheapest possible supplies of electrical energy. It is to be regretted that there is not more general publicity given to the alternative sources which are set out in the paper, particularly among works managers and directors of industrial concerns. The fact that a super-power station with an overall thermal efficiency as high as 20 per cent is very unusual at present, and that the average overall efficiency of the public supply undertakings in Great Britain is only about 12 per cent, is obviously not appreciated. With a well-designed combined power and heating scheme it is easy to attain a thermal efficiency of 60 per cent on the plant, so that obviously the private plant must be justified in these cases unless the capital charges and wages for the small power plant more than outweigh the saving due to fuel costs, and of course there is no reason why they should. To the reasons which the author gives on page 899 for certain works taking a public electricity supply, when it is certain that by doing so they are wasting the national supplies of coal and increasing their own production costs, one might add the fact that the workers in many trades have been brought up to achieve results by rule-of-thumb methods, and they raise every possible objection to any apparent change in the process-steam supply. Numerous instances could be given of operatives raising objection to the use of steam which had passed through an engine, although it corresponded in every way to the supply previously obtained direct from the boilers through reducing valves, etc. The author has not included a reference to waste-heat boilers in his paper, but there is no doubt that by their use very cheap power could be generated in many works. In conjunction with steam-driven generating plant electrical energy can be produced at a cost which is practically the sum of capital charges, stores charges and wages for the plant. On gas-works, iron and steel works, cement works and similar places, electrical energy can be produced at a figure which is very much lower than the public supply rates.

Mr. C. J. Elliott (*communicated*): I am mainly interested in the author's remarks and figures in connection with bleach and dye works. The figure of 0·756d. per unit justifies the use of a small power plant for the case cited, as the cost of current, if purchased, would be in the neighbourhood of 0·9d. per unit for these conditions. An operating cost of 0·352d. per unit, whilst liberal, is near the mark, but the capital charges are excessive for the average case. If it is necessary to spend £2 000 on pipework, probably £1 500 should be spent as a work's improvement where the works are driven by small steam engines, and this amount would have to be spent if current were purchased from an outside source. The author's capital figure could therefore be legitimately reduced to a maximum of £5 000, and as the average life of the material represented by this amount would be in the neighbourhood of 35 years the interest and depreciation figure of 10 per cent could be reduced to, say, 8 per cent, which would make the total cost per unit 0·612d. The running plant should have a minimum life of 25 years, and this is confirmed by a set running under my supervision which is 26 years old and appears to be good for another 10 to 25 years' life. It was completely overhauled 12 months ago at a cost of £100, and tool marks were still visible in the cross-head guides. Experience gained with some 25 modern high-speed reciprocating sets working against back pressure, and 15 old electric lighting plants, has proved the supply given by them to be more reliable than the supplies taken at 10 works from outside sources. In very many cases there is a field for both the private plant and the outside supply in the one works. This would be mutually beneficial to both consumer and supply undertaking, but to get the full advantage of such a combination the supply undertaking will have to adopt a broader and more commercial spirit than that adopted by many of them at the present time.

Mr. A. C. Pain (*communicated*): Considering the matter on broad lines, it is difficult to understand how anyone can advocate a system which involves the deliberate waste of 60 per cent of the heat in the fuel burned by discharging it in the cooling water, as is the case in super-power and other condensing stations. Instead of trying to establish a monopoly for such a vicious system, surely the sensible course would be to encourage the private plants, or such of them as do make some attempt to avoid this serious waste by endeavouring to utilize the heat in the exhaust steam. Other countries are wise in this respect. Herr Treitel in his paper on "German Practice in Exhaust Steam Engineering" read before the First World Power Conference, after referring to the numerous industrial plants in that country which find that they can produce electrical energy at a lower cost by combining the production of power and heat, points out that this method of operation is very desirable from the point of view of national economy, and goes on to say that so far as Germany is concerned it is becoming the exception for power plant for industrial purposes to be of the ordinary condensing type. In other words, they are there fully alive to the iniquity of wasting the heat in the exhaust steam, and keen on finding ways and means of avoiding it. If a tithe of the thought and scheming which have been put into gaining half per cents in the thermal efficiency of large power stations had been devoted to reducing or avoiding the loss consequent upon the waste of heat in the cooling water, this country would be in a very much better position than it is at the present time. The way to do this is to seek out methods of utilizing the heat in the exhaust steam, and to encourage and assist the person or firm who is able and willing to do so, instead of placing obstacles in his way and endeavouring to force him to take his energy from the public supply mains. Facilities should be afforded for anyone who can generate current cheaply by the utilization of exhaust steam to

dispose of any surplus power into the public supply mains, by running in parallel with the public supply. This would have the effect of linking up the industrial power plants and enabling the industry which requires much steam and little power to collaborate with the industry which requires much power and little steam. It has sometimes been suggested that works which require much steam and little power should be located by the side of works which require much power and little steam, but if the power plants of such works were linked up in this way there would be no need for the works to be moved. This system is already in operation to a limited extent, notably the waste-heat stations on the North-East Coast and a few private plants, but it should be extended throughout the country. Its application need not be confined to waste steam, but to waste of all sorts, including those mentioned by the author; e.g. waste gases (coke-oven and blast-furnace); manufacturing wastes (household and town refuse); and last, but by no means least, waste water power, observing that there must be many small streams which could be economically utilized if this system prevailed, in addition to the few which are already being used. Is there any other industry which has such a waste as 60 per cent connected with its activities and which, like the power industry, makes no effort to amend it?

[The author's reply to this discussion will be found on page 911.]

Scottish Centre, at Dundee, 24 April, 1925.

Mr. A. P. Robertson: The author has endeavoured to show that in certain circumstances it would be better for a works to generate its own supply of electricity than to take it from a public supply undertaking. Whilst this possesses certain advantages, especially in process work, reliability and continuity of supply are worth something. If spare plant is to be installed the capital charges are greatly increased. The space required for the generating plant must also be carefully considered. In one case a firm valued this space at £10 000 for 500 kW and in this case decided to take a public supply. The space required for a substation and switchgear is not large compared with that required for generating plant inclusive of boilers. Where steam at low pressure is required for process work it is certainly economical to use an engine or prime mover as a reducing valve, and take advantage of the power generated. I do not, however, think that the author makes out a good case for the saw-mill on page 899. The gross cost per unit is given as 1·21d., and the public supply is available at 1·25d. per unit. Nothing has been allowed for handling the material to the boilers, and if this is included the cost would be 27 tons per week at 6d. per ton, equal to 13s. 6d. per week or £37 15s. per annum. This brings the cost per unit to 1·261d., which is higher than the cost of public supply. The author suggests a stand-by supply but does not make any allowance for this, the charge for which is £2 per annum per kW or £200 per annum for 100 kW. Add this to the gross cost of £845, and we get £1 045, equal to 1·494d. per unit. Taking the public supply at 1·25d. per unit, the yearly bill would be £875, showing a saving of £170 in favour of the public supply. In addition, there would be available about 600 tons of sawdust at 16s. per ton, equal to £480, and 200 tons of firewood at £1 per ton, equal to £200, a total of £680. Allowing 50 per cent for handling and selling (a very liberal figure) there would still be available £340 which, added to £170, gives £510 per annum in favour of the public supply. There still remain the long shooter shavings and the four-cutter dubbings, which would raise sufficient steam for canteen cooking, heating and seasoning. The space required for the boiler and engine would also be saved, and in a congested area this is a valuable asset. I have taken the author's figures and have excluded the handling of refuse in both cases. Even if the power were generated by wood-refuse gas plant as detailed on page 900 there would still be a saving in favour of taking a public supply. In an article on the raising of steam from waste products it was stated that sawdust and shavings were unsuitable for steam-raising if used alone, as a great deal of ash is produced which requires very frequent cleaning of the fires and ash-pits. The best way to burn sawdust and shavings is to mix them with cinders, coke breeze or other material. Chalk and sawdust have also been used. I should be glad if the author would say how he burns his sawdust. It is possible, of course, that owing to the percentage of wood chips and other solid matter the sawdust may burn easily in this case. Turning to small, self-contained power stations, whilst a small power station with up-to-date plant could possibly generate at less than 2d. per unit, there is no margin for spare plant, and arrangements would have to be made for a stand-by supply from a large power station. Supposing that mutual arrangements were in force whereby no stand-by charge was made, the fact of the small station requiring to be run in parallel with the larger units would necessitate more robust switchgear in the smaller station. The capital charges on this would add an appreciable amount to the unit cost, and although there might be certain cases where the situation of the small station would justify its erection, I am of the opinion that in the majority of cases the large super-power station can generate and distribute more cheaply. Before any small stations were erected, the circumstances would have to be taken into account for each individual case.

Mr. J. S. Thomson: In our area we have comparatively little experience of plants using process steam. The linen industry does use process steam, but when the details of the operation of such plants are investigated it is generally found that the amount of coal required to get the process steam is very much less than has been imagined. I think the real point is one of capital charges. If the consumer takes a supply from the public mains we know what happens if the supply fails, but if his own plant fails he suffers a couple of days' shut-down without much complaint. It is fairly safe to say that every factory with a private plant has stopped for two or three days at times, some of them more than once.

If, however, they come on to our mains and we stop, they immediately threaten to supply their own power. If they put in duplicate plant the cost would be very different. The author really arrives at his figures by making considerable use of the public supply, but whilst the principal object of a public supply undertaking is to do a public service, I do not think it is one of its aims to enable people to show what they can do with the supply undertaking's assistance and at the expense of other consumers. It is a very difficult subject; it is so easy to make out a case for anything. Taking my own company, for example, during the past 20 years only two consumers have gone off the mains, except, of course, those who have gone out of business altogether. One of these is, I know, very regretful that he did so, because he has already lost more money than would drive his works for years, and he is not finished yet. In the case of the ordinary simple self-contained station, there I think the question turns on two things, stand-by supply and load factor. Only last week I had an inquiry in respect to a 400-kW job. The applicant said that our prices were impossible, and in the course of the conversation it appeared that his argument was based on a 60 per cent load factor, whereas the load factor for the previous year was actually only 32½ per cent. On this basis his own figure was considerably higher than the figure we were offering, which was eventually accepted.

Mr. E. Seddon: In detailing the various items which make up the cost of the private plants, the author makes no allowance for buildings or spare plant, the inclusion of which would materially increase the capital costs of these small plants. When comparing these costs with the conditions obtained where a public supply is taken, some allowance should be made for the site value of the owner's plant. I submit that the author does not appear to have allowed a sufficient amount to cover wages for labour required in operating the various plants. The statement at the top of page 898 shows that other portions of the works are bearing certain costs for operation which should properly be allocated to the power plant. There is one class of power consumer which most central station engineers will agree is difficult to obtain as a consumer. I refer to a manufacturer who requires steam-heating for process work for such trades as papermaking, brewing, etc. Owners of private power plants do not as a rule put sufficient value on the reliability of energy supplied by the public authority. When private plants break down there is usually no alternative to closing the works until such time as the repairs are effected, whereas the chances of an interruption of public supply, except for a short period, are very remote, due to the fact that spare plant is held in reserve to meet emergencies. Fortunately for the whole community, private power plants with their attendant nuisance from smoke and dust are daily becoming fewer in number. Regarding the cheapest form of power, it is of course fully realized that each case must be worked out on its merits, as the cost of electricity varies so much as between different districts.

Mr. D. J. McDonald: Mr. Robertson has not stressed too highly the value of space, and I think that the paper does not give this point sufficient value. In any city space must be taken into account in every case in calculating the cost of generating the current. On the other hand, Mr. Robertson makes far too much of the stand-by plant. For that, however, not he, but the whole electrical engineering industry is to blame. When plants are put down the margin of power is in many cases far too small and the liability to breakdown far too great.

Prof. A. R. Fulton: There is no doubt that in certain circumstances small power plants can be used, but it is very doubtful whether they can successfully compete with the Dundee Corporation supply.

Mr. W. Sutcliffe: Experience has, I think, proved beyond dispute that in paper mills where a large quantity of process steam is required it is possible for a private plant to generate energy at considerably lower charges than could economically be offered by the nearest public supply undertaking. There are many successful examples of private plants in Scottish paper mills, and it is significant that at the moment there are to my knowledge three cases where such private plant is being installed. At the same time, however, many cases arise in which the demand for process steam is comparatively small; here the question as to whether a private plant should be installed depends very greatly on the prices that would have to be paid for current if purchased from outside. Power charges vary within wide limits in this country, certainly from 0·5d. to 2d. per unit, frequently depending on the views held by the local supply engineer. It is therefore obvious that what might be the correct thing to do in one district would be entirely wrong in another part of the country if the prices quoted in the two districts were low and high respectively. This point should be fully considered before coming to a decision regarding private plant versus public supply. Incidentally, I suggest that the wide discrepancy in supply charges for power throughout the country might be brought under review by the Electricity Commissioners, because at present we have the anomalous position that whilst manufacturers must compete in the price of their finished products, one of them, through no fault of his own, may have his operating costs made considerably higher than his rivals' owing to having to pay more for his power supply. The standardization of electricity charges, particularly for power purposes, is to my mind just as important as the standardization of frequency, and it is to be hoped that when the latter is accomplished the other will follow. Referring to the typical saw-mill installation cited by the author on page 899, my own view is that this particular example is not one which would warrant inclusion in the category of "Justifiable small power plants," because, according to the author's own showing, the difference of price in favour of the private plant amounts to 0·04d. per unit, or, assuming 168 000 units per annum, a matter of £28. I would suggest that it might have been preferable to have utilized the £3 600 capital expenditure on the plant in a better way by putting the money into the saw-mill business for development purposes, in which case presumably a return of anything between 10 and 15 per cent would have been shown. Assuming the minimum of 10 per cent return, the financial results would have been sufficient to turn the scales in favour of the public supply, unless the cost of handling and disposing of the refuse were considerably

higher than might be expected. It is probable, however, that in the near future our views regarding private as against public supply will undergo modification if the cost of energy falls to, say, ⅜d. per unit, even in the most remote hamlet, as a result of electrical developments consequent upon the proposed linking-up of the various supply stations throughout the country.

Mr. D. H. Bishop: In coming to a decision in any engineering problem a compromise has almost always to be made between some advantages and some disadvantages, and there are often factors whose value is difficult to express exactly in terms of money, e.g. convenience, saving in space, etc. We find that managers of works are in general very glad to rid themselves of the responsibility of generating plant. The cost of power is, after all, a comparatively small part of the total expense, and they naturally prefer to concentrate their time and energy on their own business, which is the more important part. Those of us who are intimately connected with power stations know what constant vigilance is required to keep the efficiency of the plant up to anything approaching the purchase guarantees, and I maintain that it is almost impossible to do it in the case of small works. A case may be made out on paper for a small power plant, but what really matters is not what the plant should do but what it actually will do in the course of years—a very different thing in practice. On the question of spare plant there is a difference of opinion. I am one of those who think that spare plant is necessary. I do not see how the efficiency of a modern, efficient plant can be kept up without an occasional overhaul. With the old, inefficient types it did not matter so much, but modern plants are much more delicate mechanisms, and not only fall in efficiency but may also actually refuse to go at all unless regular overhaul and adjustments are made, all of which take time. On page 897 the author mentions the way in which the case is put by the power supplier, but I suggest that the way in which the prospective power consumer states his case is equally important. We have found in a large number of cases which have changed over to a public supply that the units actually used and paid for are very much less than (sometimes only one third of) the amount the consumers said they would require. Their estimates of their costs per h.p.-hour were therefore greatly exaggerated. There are doubtless some cases in which a fair-minded engineer would agree that a private supply is advantageous, but only a few will come in this category.

Mr. A. B. Mallinson (*in reply*): This discussion has centred generally on (1) The general principles of small power stations as against super-power stations; (2) criticism of the capital and operating costs quoted; and (3) general comments on the various types of justifiable small power plant referred to in the paper, and I shall reply seriatim to the various points raised under those headings.

(1) *The general principles of small power stations as against the super-power station.*

Doubtless from the supply station engineer's point of view this paper is in general looked upon as "rank heresy," and I fully expected the storm of criticism from that source which arose in the discussion. There are, however, two sides from which the subject should be viewed; and in the paper I have endeavoured to show from the consumer's point of view how the source of supply of power can affect his individual industry. The other main point was national economy; the whole justification for the small power plant rests on these two factors, and particularly the latter.

There has been during the past two years far too much loose talk in the lay Press of super-power stations, which are going to make electric power available everywhere at such a price that industry will leap ahead, unemployment disappear, etc.

Several speakers, whilst agreeing that the small power station on waste-fuel or heat-economy lines is justified, have referred to the "straight power station" as being an indisputable case for the super-station. To be fair, however, the comparison should be made on the same basis, i.e. the super-power station prime mover of 1925 and the small power plant unit of the same period. To compare obsolescent small stations in which the units have steam consumptions of 15–40 lb. per kW is absurd. There is no difficulty in attaining a consumption of under 12 lb. per kW on sets of 2 000 kW to-day, and even on units of 100 kW a consumption of 15 lb. per kW is possible.

Messrs. Aylmer and Sills refer to the policy of the Electricity Commissioners as the rule we should all follow, and in general this is undoubtedly correct. The recommendations made by that technical body, however, when passed from one Government department to another, are liable to be used to force a line of action by a non-technical body, quite contrary to the national interests. The super-power station has undoubtedly a very large field to fill, but to apply its principle to all cases must mean that many manufacturers will pay far more for their power than would be the case had they produced it themselves.

Messrs. Watson and Lamb cite the fact that numerous works have taken a public supply when they used steam for process work as proof that the outside supply is the cheaper and better. My experience is that in the majority of such cases either (*a*) the works have never realized the potential source of cheap power that they have, or (*b*) that the limitation of capital expenditure has been the deciding factor.

Messrs. Watson, Medlyn, Lamb, Robertson, Thompson, Seddon and Bishop speak of the greater reliability of the public supply. Mr. Herbert, on the other hand, points out that in the case of telephone exchanges, where continuity of supply is essential, "fortunately, the use of secondary batteries means that there are several hours available in which to make the necessary arrangements." Undoubtedly power stations in general now give a very reliable supply, but it is doubtful if it can be said they are any better in this respect than a modern well-laid-out works power plant would be. Within a few days of this paper being read in Manchester, we had an example of the dislocation of operations in a town due to a power station breakdown. Many large manufacturers have instanced to me their desire to generate their own power purely and simply from the points of view of safeguarding continuity of opera-

tion, a factor of vital importance with the present trend of organized sympathetic strikes, etc. Mr. Christianson quotes similar examples.

Messrs. Watson, Robertson, Thompson, Seddon and Bishop raise the question of spare plant and compare the advantage of the public supply in this respect with the great risks undertaken in operating a small plant without such spares. As Mr. McDonald rightly points out, this is a very weak criticism. If one installs a mechanical drive in a factory, one does not put in a stand-by drive. Or, again, if one electrifies a works from the public supply, does one install a stand-by motor on each drive? Of course not! Why, therefore, if there is a dynamo between the engine in the one case and the motors in the other example, must there be a stand-by? Such arguments indicate little faith in the reliability of electrical plant.

Messrs. Clarke and Medlyn quote cases where advantages have been secured by shutting down small plants—there are thousands of such cases. The same remark applies to the power station; plants installed 15 to 25 years ago are not comparable with what is possible to-day.

Messrs. Lamb and Seddon speak of the nuisance which private plants, with their smoke and dust, are to the community; but there is no difficulty in operating the private plant with a clean stack. The paper mill quoted on page 897 burns some 600 tons of coal weekly with no sign of black smoke (there used to be plenty before the plant was modernized); whilst a colliery plant which I inspected last week, raising an average of 40 000 lb. of steam per hour, has a stack only 75 ft. high, and has been in use night and day for four years, yet the mortar in the stack courses is quite white up to the last ring of brickwork. The saw-mill case is quoted by the Medical Officer of Health in the district as an example of how refuse can be burnt without producing black smoke, one of the principal culprits being a similar works, operating on the public supply, who burn their refuse to get rid of it.

Messrs. Lamb and Thompson take me to task on the subject of stand-by supply. There is no question of getting anything without paying for it—surely the right way to look at these matters is from the national point of view. As Mr. Frith points out, often it is only by installing a public supply that a firm can remodel their layout and install a plant to produce their power from waste. Mr. Crews speaks of many cases where he has been able to arrange alternative supplies on the lines advocated.

The feeding back to the supply system of surplus power so generated is equally desirable, but can easily be so surrounded by difficulties in the way of complicated switchgear, etc., demanded by the supply undertaking that it becomes impossible; if approached in an open-minded manner there are appreciable developments possible in this direction. In numerous cases during the past few years the scheme has operated satisfactorily. The attitude sometimes taken up by supply undertakings with regard to firms generating part of their supply, has been criticized by the power station advocates, but my remarks in this respect are confirmed by Messrs. Sills and Baker, who have experienced the same difficulty.

(2) *Criticism of the capital and operating costs quoted.*

Capital cost.—Messrs. Watson, Tustin and Seddon challenge the non-inclusion of the capital cost of steam-raising plant in the heat-economy examples. Apparently they overlook the fact that the comparison is merely the cost per unit basis as against the cost of outside supply. If their view were right, one should equally add to public supply the proportionate charges on the capital outlay of the heating plant. Mr. Watson's suggestion that the boilers might equally have first been installed for power and then used for heating is doubtless correct in many cases, but we must consider the user's requirements as a whole. If he requires heat and power he cannot carry on with one alone, therefore if the outside supply cannot supply the steam for heating he must have his own steam-raising plant and then consider the power question separately.

Capital outlay.—The capital cost of the examples quoted has been criticized, Mr. Lamb stating that the capital outlay of the most expensive 25 000-kW turbo set was about one-quarter the price quoted in the paper. The average of the six cases given is £28·1 per kW. In the *Electrical Review* the cost of the new Ribble power station of 25 000 kW is given as £450 000, i.e. £18 per kW, plus £100 000 added for mains, or £22 per kW. Mr. Elliott points out that in the case of the dye works probably 25 per cent of the total outlay quoted would be a works improvement if this amount had to be spent to bring the present steam distribution system into line. This is no doubt correct; the case quoted was an extremely bad existing equipment. Mr. Christianson considers the amount allowed for the power plant in the case of the paper mill to be too high. The figures throughout the paper were purposely kept high to represent installed plant costs.

Labour.—Many speakers in the discussion consider the labour costs to be insufficient. The cases quoted (with one exception, the mental institution) are actual operating plants; in the case of the mental institution the estimated labour cost has since, as the result of inquiry, been further reduced.

The non-inclusion of labour cost for steam-raising on heat-economy plants is challenged by Messrs. Watson, Dundas and Seddon, but I cannot agree with their view. Either the cost of bought power must be compared with the cost at which it is possible to generate, or the comparison must be on a *thermal* basis pure and simple, the cost of bought power being added to the cost of steam-raising for heating. If this latter course were easy it would be the better way, but I fear that it would prove a shock to many manufacturers now on a public supply.

Trained staffs.—Mr. Medlyn speaks of the risk of operating without a trained electrical staff, but let us consider the evolution of the works-driving layout. In the old days with a mechanical drive an engine tender lubricated the engine by hand, the maintenance in general being in the hands of the works engineer. If motors were installed and a public supply taken, either the works engineer or a labourer looked after them, or, if the installation were sufficiently large, a works electrician. In any case the wages of such staff

do not affect the cost per unit of the public supply. If a firm generates its own power, surely the addition of one or two dynamos does not necessitate a trained staff. An up-to-date dynamo requires no more maintenance than an average motor.

Maintenance.—As Mr. Watson points out, the battery maintenance in the one case quoted had been omitted. This has now been added.

Insurances.—The insurances given in the paper were for boilers and engines, not motors, as they are common to both supplies.

Depreciation.—In reply to Mr. Medlyn, all the examples quoted have been worked out on the common basis of 10 per cent, i.e. 5 per cent interest and 5 per cent depreciation.

Local rates.—Mr. Watson refers to the lack of allowance for local rates. These were purposely not referred to in the tables given, because it is difficult to see how they would affect the case. To replace an old power plant with a new one is different from installing a new power plant as an extension to a power station existing solely for generating power. I am not aware that any reduction is made in the local rates if a works scraps its own power plant and purchases power.

(3) *General comments on the various types of justifiable small power plant described in the paper.*

(*a*) *Water.*—Mr. Watson's remarks on the possibilities of power in the flow of the Irwell as shown from the records taken are extremely interesting. This is just one of probably at least a hundred similar rivers available in this country.

I entirely agree with Mr. Frith in regard to the difficulties which arise in attempting to make use of water; sooner or later compulsory powers will have to be provided for this purpose.

(*b*) *Air.*—Since the paper was written there have been some interesting developments on the Continent in this respect. The new knowledge of the air forces attained in the perfection of the aeroplane, coupled with the development of automatic switchgear, undoubtedly open possibilities for interesting advance in this respect.

(*c*) *Heating and process steam.*—In the case of the paper mill, Mr. Medlyn refers to the fact that there is no provision in the operating costs for the handling of 560 tons of coal. This appears to be a great deal, but it is only about 2 per cent of the coal handled at the boiler-house of this mill. The coal is dumped by a wagon tipper and then elevated to the overhead bunker. At the most a few shillings would cover all the cost. Mr. Lamb, working from the ash figure, calculates the boiler efficiency to be 80 per cent, and compares that with Mr. Brownlie's figure of 58 per cent. Notwithstanding Mr. Brownlie's figures, I know at least two paper mills about this size in which the boiler efficiency with Lancashire boilers is regularly 74 per cent. Mr. Lamb's calculations are at fault in assuming that there is no combustible matter left in the 20 per cent ash. Actually the calorific value of the coal is 12 500–13 000 B.Th.U. The operating condition for the paper mill is 0·5 lb. not 5 lb. per kW as pointed out by Mr. Dundas.* He, however, has not grasped the need for the 560 tons of coal charged to power; it is not that the demand for power is greater than the demand for heating, but that a liberal allowance is made for steam which is lost by condensation, etc., in the prime mover and which is therefore not available for heating.

The remarks by Messrs. Baker, Baldwin, Elliott and Pain on the question of heat economy are much to the point. These gentlemen speak with practical experience of the operating results of such stations in all classes of industry, and whilst it might be said that some of them, being connected with the manufacture of engines, are biased, the same remark applies equally to the criticism of the various supply engineers.

Mr. Elliott's remarks, coming from one with considerable operating experience of back-pressure power plants, are extremely interesting. It will be noted that his comments on the capital and operating costs for the bleach and dye works are that the capital cost is too high and that the operating costs are near the mark but liberal.

As Messrs. Baldwin and Pain point out, there surely cannot be any case for argument when the power station average efficiency to-day is of the order of 12 to 20 per cent or so for the latest super-power station, yet a small heat-extraction station can run at 50 to 60 per cent efficiency.

I entirely agree with Mr. Pain's suggestion that private plants to operate on these lines should receive similar encouragement to the super-station; sooner or later the point will have to be dealt with. If a tithe of the expenditure now being incurred on many of the post-war so-called improvements were spent on such lines the improvement in the country's national operating efficiency would provide a handsome return.

Mr. Baldwin mentions the objection of workers to any change in their operating system. This is very often met with. Numerous cases have arisen of objections, for instance, to the direct use of exhaust steam for cooking; tact in introduction and a carefully thought-out layout are essential in the starting-up of such plants.

The public institution described by Mr. Rothwell is typically a case for a heat-extraction plant, yet it is somewhat surprising to find the Ministry of Health now look with disfavour on such equipments, presumably owing to pressure being put on them to support the public supply undertakings.

(*d*) *Power plants operating from process refuse.*—The principal case discussed is the typical saw-mill installation quoted on page 899. Mr. Watson, who knows the installation quoted, is in cordial agreement.

Messrs. Medlyn, Lamb and Robertson have endeavoured to show that this installation would far better have been left to operate from the public supply, the primary objections raised being:—

(i) That there is so little difference in the costs of generated and bought power.

(ii) That no allowance is made for the stand-by supply in the operating costs.

* This figure has since been corrected.

(iii) That no allowance is made for handling the refuse.
(iv) That if the public supply has been installed, the refuse could have been sold and additional revenue so obtained.

As it happens, this particular installation has been operating both ways. For a period of four years it was operating on the public supply, an old Lancashire boiler being retained to drive a small non-condensing engine of about 40 h.p. The boiler was fired with unsaleable waste refuse, helped out with coal if required. Since this plant has been put in it has been operating for 2½ years under the new system, with a 160-h.p. steam locomobile driving the bulk of the works, a 75-h.p. motor being retained direct on the town supply for a separate part of the works. The average actual operating results per year on the two systems are as follows:—

SAW-MILL OPERATING COSTS.

		4 years on public supply		2½ years on own supply
Bought electricity ..		£829		£444
Stand-by charges ..		—		66
Coal used in addition to wood refuse ..		171		—
Oil		26		35
Water		12		15
Labour (all engineering services for mills) ..		607		802
Insurances (boiler) ..		8		15
Maintenance		35		50
		£1 688		£1 427
Value of waste sold:—				
Firewood	£40		£93	
Sawdust	£523		£548	
		563		641
Net cost ..		£1 125		£786

It will be noted that when operating on public supply, owing to the inefficient way of burning the refuse, in addition to burning as fast as a man could fire, working hard all the time, a considerable amount of coal had to be bought. The value of refuse sold since the private plant was put in is greater than the refuse sold when the public supply was used. The only extra labour required has been the addition of an engine tender to look after the engine.

The figures for electricity include stand-by electricity, and are worked out on to-day's basis rate per unit. On page 899 the outlets through which this refuse can possibly be sold are indicated. There is only a limited demand for the bulk of the refuse produced, i.e. sawdust. Much of the refuse produced in wood manufacture is entirely unsaleable, and many works now operating on public supply have a boiler fired simply to get rid of this refuse, and make practically no use of the steam so raised. The handling of the refuse does not enter into the question; it is impossible to operate the mill without handling the refuse, whether the supply is public or private.

Mr. Robertson mentions the great amount of ash produced when burning wood refuse, and suggests that the best way is to mix it with cinders, coke or other material. My experience is that this is entirely wrong; there is remarkably little ash from burning straight wood refuse, and what there is is an excellent fertiliser, being specially suitable as a reviver for golf putting greens and grass lawns. To mix it with a hard fuel such as coke, breeze or cinders is most inadvisable. The whole secret of burning wood refuse lies in the design of the furnace; it is utterly impossible to do it in the ordinary fire-tube boiler or even in an extension furnace in front of it. The method employed in the plants quoted is to have a large underground step-grate furnace, where the refuse is fed in at the floor level, dries on the upper steps of the grate, and is then gradually pushed down into the fire zone and consumed, only the flames and hot gases passing through the boiler.

The grate area of the 160-h.p. plant quoted is 27 sq. ft., and the boiler pressure 174 lb. per sq. in.; the steam is superheated to a total temperature of 660° F.

(*e*) *Waste-heat boilers.*—Messrs. Frith and Baldwin comment on the manner in which power can be produced by waste-heat boilers. There have been many fine plants installed on these lines but, having no personal experience of them, I only lightly touched on the subject.

With regard to blast-furnace gases and gas engines or steam turbines, there are of course advocates for each method; my experience is that the apparently lower thermal efficiency of the boiler and turbine is more than counter-balanced by the greatly reduced maintenance and labour operating costs.

(*f*) *Household and town refuse.*—I agree with Mr. Watson that many of the installations installed in this country have been complete failures, but I would suggest that if such plants were re-developed on present-day lines, bearing in mind the various ways (apart from production of steam) in which such plants can produce revenue, there would be more done in that respect. In Germany there have been some very striking developments on these lines in the past few years.

(*g*) *Simple self-contained power stations.*—After carefully reading the remarks made by various speakers on this type of plant, I am more than ever convinced that there is a very strongly debatable case for the straight power station in many instances—either as a private plant, or as a public supply operating against the public power station. In the case of the private plant, such an installation can generally be installed to operate at a far better load factor than the average central station can hope for. Mr. Robertson speaks of a possibility of operating at about 2d. per unit; if such a figure were divided by 2 or 3 it would be nearer the figure which is actually being obtained.

For a small public supply station the bugbear of low load factor would doubtless apply, but, as already indicated in my reply, the developments in economy of small power units during the past few years have been remarkable, and it is quite impossible to make any comparison on plants dating back even a few years.

Finally, I would again emphasize the conclusions mentioned in the paper. If small power plants are to be successful, when being installed they must be regarded as one part of the complete operating equipment of the factory, with just the bare necessities required for producing the quantity of power called for, no elaboration on buildings, switchgear, duplicate plants and pipe lay-outs being allowed. In operation the plant should be given a chance to operate as it is designed to operate, i.e. with the minimum of attention. I would particularly draw attention to the remarks made by several speakers with regard to trained technical staff and the like. To go on these lines is courting failure. Prime movers as designed to-day will operate with the minimum of human attention, and there is absolutely no need, just because a dynamo is connected to the engine, to encourage the development of staffs on the lines of miniature central stations.

PROCEEDINGS OF THE INSTITUTION.

728TH ORDINARY MEETING, 19 MARCH, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 5th March, 1925, were taken as read and were confirmed and signed.

Messrs. E. S. Ritter and E. S. Shoults were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:—

ELECTIONS.

Associate Members.

Bainbridge-Bell, Labouchere Hillyer, B.A.
Ball, Hereward Thomas S.
Blackman, Thomas Mainwaring.
Caldwell, Athol Ceadric A., B.E.
Hall, Eustace.
Ullrich, Edward Hill, B.A.

Graduates.

Bowler, Frank Colman, B.Sc.
Cameron, Alexander Robert, B.Sc.
Chambers, Edward Andrew.
Clarke, Albert Stanley.
Clarke, Arthur Roy.
Davies, Edward Gordon, B.Sc.
Goodier, William Richard.
Miller, David, B.Sc.
Minter, Robert William.
Murray, Ian Norman, B.Sc.
Parsons, Enoch Herbert.
Prickett, John Howard.
Sandys, George Henry.
Sard, Percy John.
Williams, Fred.

Students.

Adams, James Lewis M.
Anderson, Ernest William.
Anderson, John Rupert.
Andrews, Desmond.
Avery, Richard Leslie.
Baird, Robert William.
Barrett, Reginald James, B.A.
Bassett, Frederick Joseph.
Beaver, Roland Victor.
Bevan, Gilbert William.
Black, John Arthur.
Brassington, Edgar George.
Brooks, John.
Buckingham, Herbert Betts.

Students—continued.

Buckle, George William V.
Bullard, Horace Charles F.
Burdick, Robert Harry.
Calvert, Paul John.
Charlton, Walter Winlow.
Chatterjie, Hemen.
Cliff, James Stanley.
Coleman, Walter Robert.
Copeland, Robert.
Daniels, Frederic William.
David, Trevor.
Dorte, Philip Hoghton.
Dunn, Wilfrid Kenneth.
Edwards, Norman.
Eunson, John.
Evans, Frank.
Fitt, Cecil George.
Freeman, Charles Davis.
Gajjar, Harivaden Chimaulal.
Gerard-Boulton, Arthur.
Gillitt, Richard.
Gosland, Leslie.
Graham, John Aidan I.
Gray, Reginald Arthur G.
Grove, Peter Fayle, B.A.
Harbridge, Alfred James W.
Hart, Donald Alfred.
Heelis, Arthur James.
Hirons, John William.
Howarth, Sydney.
Howton, Sydney Charles.
Hunter, John.
Ife, Harold James.
Johnson, Percival Leigh.
Jolly, Thomas Herbert, R. H.
Jones, Howard Edward.
Keogh, Hubert Hedigan S.
Lambert, William.
Linley, Frank.
Lipscomb, Robert.
MacAlister, Alexander Frederick.
McDouall, Patrick Sutherland.
Mayes, Guy Noel H.
Metcalfe, Sidney.
Middleton, William John B.
Morris, Alfred James.
Morris, John Common.
Mountfort, Louis Vincent.
Moyes, John Edwin A.
Netherwood, Reginald.
Oddy, George Naylor.
Ord, Thomas Charles.
Osman, Abdelsalam Ahmed.
Palin, Frederick James.
Parrott, Thomas Henry.
Patel, Motilal Lallubhai.
Payne, Charles Ernest.
Peggs, Eric Percy G.
Rendle, Harold Barton.
Rickard-Smith, Hugh John.
Roynon, Frank Goodner.
Rushton, Eric, B.Sc.
Sabaretnam, Charles Victor W.
St. George, Reginald Graham.
Scott, Edward Chalmers.
Shackleton, Herbert.
Shaub, John Frederick H.
Smith, Frederick Wilce.

Students—continued.

Smith, Wilfrid Cyril.
Spiller, Richard Lucien.
Stirrat, James.
Strong, Albert Edward, B.Sc.(Eng.).
Thomson, George.
Tiffin, James Eynon.
Turner, Arthur Cecil.
Turner, John.
Webber, Francis Douglas.
Webber, William Rudston.
White, Kenneth.
Wilkinson, Kenneth James R.
Wimshurst, James Allan.
Wise, John Boles.
Young, Robert.

TRANSFERS.

Associate Member to Member.

Spence, Harold Cruickshank.
Stahl, Henry Cecil.
Steele, William Herbert.
Ward, Mark, B.Sc.(Eng.).

The President: My next duty is a very pleasant one. We are here to-night to do honour to Sir Joseph Thomson by presenting to him the Faraday Medal of the Institution. Before making the formal presentation I shall ask Dr. Eccles to say something about the scientific work of Sir Joseph Thomson.

Dr. W. H. Eccles: This Institution has always been eager to acknowledge its debt to men of science, perhaps because many of its members have been devoted both to science and to engineering, or perhaps because application follows science more quickly in electrical than in any other branch of engineering. In our subject the theory of to-day becomes the practice of to-morrow, and in a few years the laboratory experiment becomes the essence of great industries, involving the expenditure of hundreds of thousands of pounds and affecting the well-being of millions of people. It is probably for all those reasons that the Council, in establishing the Faraday Medal, made it available not only to engineers but also to men of science. The name of Faraday in connection with this Medal has its significance. Faraday was a practical man in his manner of thinking. He insisted on visualizing electric and magnetic fields by forming a mental picture of lines of electric and of magnetic force which by their motion or their mere presence produced the various effects that have been collected into his theory of electricity and magnetism. I know that the Continental mathematicians and physicists sometimes gibe at the English method of thinking about abstract things by aid of a working model, but the fact is that the engineer, whether he be foreign or native, finds the conception of lines of force exceedingly useful and designs electrical machinery by aid of that conception. In due course, after Faraday, Maxwell produced his mathematical theory, and he was followed closely by J. J. Thomson, this year's recipient of the Medal. If we look at some of Thomson's writings of 30 years ago, and especially if we open the pages of his "Mathematical Elements of Electricity and Magnetism" on which many of us were nurtured electrically a generation ago, we can see that he was not only an interpreter of Maxwell but also a follower of Faraday, because throughout that book the conception of lines of force at rest and in motion is the keynote. After the "Mathematical Elements" came "Recent Researches," the most famous of all electrical books in the generation which followed Maxwell. These interpretations of Maxwell and of Faraday in the practical spirit which appeals so strongly to the electrical engineer might be enough to justify our Institution in conferring this medal upon Sir Joseph Thomson. But I think it is not only because he is a descendant of Faraday in the electrical sense that the Council thought of tendering him this honour. His original papers, spread over the past 30 years, have been so far-reaching, were so full of new calculations, new experiments and new speculations, that they have had profound effects on electrical thought, electrical practice and electrical discovery. "Discovery" I might define as the exploration of the unknown. We, as an Institution, are not interested in that directly. We are interested more in application and invention; but discovery is the raw material of invention and application. If there were no discovery in electrical science, then this Institution and the electrical industry would stagnate. The fact that Sir Joseph Thomson can rank as a great discoverer need not be elaborated. If I were asked to name only two or three of his great discoveries I should say that a principal one is his conception of electromagnetic mass—the electromagnetic inertia of a moving charge. That was the starting point of the revolution in electrical thought which culminated in

Einstein's work. Again, Sir Joseph was certainly the first to realize the importance of the electron, and, having realized it, he breathed into his students at the Cavendish Laboratory inspiration and energy which provoked the admiration of the world and produced another revolution of another kind in experimental physics. A further series of papers which excited very great attention some 20 years ago were those in which he showed how, from the electron theory of the atom, many of the chemical properties of matter can be deduced. I am leaving out quite a number of great conceptions, such as that of positive ray analysis; but I have mentioned those discoveries which I think will convince the members that in his fundamental work on the physics of the universe, J. J. Thomson has made himself an immortal name, which will splendidly sustain the lustre of the growing roll of Faraday Medallists.

The President: I think that it is fitting that I should say just a few words in regard to the Faraday Medal. The Faraday Medal of this Institution was founded in 1921 to commemorate the 50th anniversary of the first meeting of the Society of Telegraph Engineers. The Medal is awarded by the Council either for notable scientific or industrial achievement in electrical engineering, or for conspicuous service rendered to the advancement of electrical science, without restriction as to nationality, country of residence or membership of the Institution. The Medal has been awarded before to-night on three occasions—on the first occasion to the late Mr. Oliver Heaviside, on the second occasion to the Hon. Sir Charles Parsons, and on the third occasion to Dr. S. Z. de Ferranti. I now have very great pleasure in asking Sir Joseph Thomson to accept this Medal and this certificate commemorating the award.

The President then presented, in the name of the Institution, the Faraday Medal to Sir Joseph Thomson.

A paper by Mr. S. Evershed, Member, entitled "Permanent Magnets in Theory and Practice" (see page 725), was read and discussed and, on the motion of the President, a vote of thanks to the author was carried with acclamation. The meeting terminated at 7.55 p.m.

45TH MEETING OF THE WIRELESS SECTION, 1 APRIL, 1925.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 4th March, 1925, were taken as read and were confirmed and signed.

A paper by Major A. G. Lee, M.C., B.Sc., and Mr. A. J. Gill, B.Sc., Members, entitled "The Leafield Coupled Arc" (see page 697), was read and discussed.

On the motion of the Chairman a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.35 p.m.

729TH ORDINARY MEETING, 2 APRIL, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the meeting of the 19th March, 1925, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 423) was taken as read and the thanks of the meeting were accorded to the donors.

A paper by Messrs. G. Wilkinson, Member, and R. McCourt, entitled "Electricity Supply Tariffs: Their Simplification by Discrimination" (see page 850), and a paper by Mr. H. M. Sayers, Member, entitled "Electricity Supply Tariffs" (see page 845), were read and discussed.

On the motion of the President a hearty vote of thanks was accorded to the authors, and the meeting terminated at 7.55 p.m.

730TH ORDINARY MEETING, 23 APRIL, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 2nd April, 1925, were taken as read and were confirmed and signed.

Messrs. T. A. St. Johnston and A. Travers were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows:—

ELECTIONS.

Members.

Greenham, George Frederick.
Mercer, Charles James.
Parker, William.

Associate Members.

Baker, Eustace Elwell.
Benjamin, Henri Lionel, B.E.
Boys, Geoffrey Vernon, B.A.
Clark, Richard Michael, B.Sc.(Eng.).

Puckle, Owen Standidge.
Robinson, Richard Edward.
Stephenson, Robert Maxwell, B.Sc.

Messrs. J. Coxon, P. Dunsheath and W. L. Wreford were appointed scrutineers of the ballot for the election of new Members of Council.

A paper by Messrs. K. G. Maxwell and Allan Monkhouse, Members, entitled "Recent Improvements in the Insulation of Electrical Machinery" was read and discussed.

On the motion of the President a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.55 p.m.

THE MEASUREMENT OF FREQUENCY AND ALLIED QUANTITIES IN WIRELESS TELEGRAPHY.

By Lieut.-Col. K. E. Edgeworth, D.S.O., M.C., Royal Signals, and
G. W. N. Cobbold, M.A., late R.E., Associate Member.

(*Paper first received 11th November, and in final form 23rd December,* 1924; *read before the* Wireless Section *4th March,* 1925.)

Summary.

It has been customary during the past three decades to define the oscillation-frequencies of "wireless" in terms of the lengths, in metres and kilometres, of the corresponding ether waves.

During the past few years there has arisen a tendency to abandon the indirect definition and to state the frequencies themselves, in cycles per second or in kilocycles per second.

The paper suggests as a further alternative the description of frequencies in terms of "pitch," a term which is defined as a relationship of the particular frequency to some standard frequency.

The proposed standard is the frequency of 1 cycle per second, and the relationship suggested is such that the "pitch" is a logarithm of the ratio between these frequencies.

Some of the possible advantages of the use of "pitch" are described, and particular emphasis is laid on the advisability of employing it in the case of very short waves.

We owe a great debt of gratitude to the pioneers of electrical theory for the care with which they selected and defined the important fundamental units employed in all branches of electrical science. The same fundamental units provide the basis for all measurements in wireless telegraphy, but the very rapid development of this last-named science has necessitated considerable additions to existing nomenclature, and many new terms and units have sprung into existence. It is not surprising, therefore, that experience is showing that some of these new terms and units are not entirely convenient.

The employment of the expression "wave-length" to describe not only the actual wave-length of the disturbance in the ether but also the frequency of the corresponding oscillations which occur in closed circuits, was a natural development, but by no means a logical one. It is now being suggested that to measure frequency in cycles per second or kilocycles per second provides a more appropriate and convenient standard than to measure wave-lengths in metres or kilometres. It seems, therefore, to be a convenient opportunity for inquiring whether cycles per second and kilocycles per second really furnish the final and most appropriate solution, or whether other alternatives do not merit examination.

In this connection it is interesting to note that the problem of standardizing and comparing frequencies is a very old one, which reached a high degree of perfection in the art of music many centuries before wireless telegraphy was thought of. It seems worth while considering whether the new science of wireless telegraphy might not profit by the teachings of previous experience.

In the art of music it is not customary to compare notes of different pitch by means of frequency measurements in cycles and kilocycles per second. Their relationship is expressed in terms of the "interval" between them, which is measured in octaves or fractions of an octave, and the object of this paper is to suggest that, for the purpose of wireless telegraphy also, the octave may possibly be found more convenient than either the metre or the kilocycle per second. The subdivision of the octave into 1 000 parts which might appropriately be described as "milli-octaves" should provide all the accuracy which is likely to be required in practical work for many years to come.

If P denote the number which we have decided to measure in octaves, f the frequency in cycles per second, and K any arbitrary basic frequency, then these quantities are connected by the equation

$$f = K \times 2^P, \text{ or } P = \log_2 (f/K) \quad . \quad . \quad . \quad (1)$$

For the purpose of this paper it is necessary to give a name to the term P in the above equation, and it is proposed therefore to call P the "pitch" of the note.

It is perhaps fortunate that the art of music has never adopted an absolute standard of pitch, and it is therefore possible to make K unity in Equation (1), and thus to write :—

$$f = 2^P, \text{ or } P = \log_2 (f) \quad . \quad . \quad . \quad . \quad (2)$$

This equation defines an absolute scale of pitch.

For every point on the scale of frequency there is a corresponding point on the scale of wave-length, and Equation (2) defines a corresponding point on the scale of pitch.

Pianos are usually so tuned that the middle C has a frequency of 256 cycles per second, and the "pitch" of this note on the scale now proposed is therefore 8 octaves.

Passing to the frequencies in common use in wireless telegraphy, a frequency of 500 kilocycles per second, corresponding to a wave-length of 600 m, would have a pitch of 18·932, and existing practice would cover pitches from, say, 13 octaves (36 620 m) to 26 octaves (4·47 m).

Finally it may be noted that the pitch of the light waves which constitute the visible spectrum extends from about 48·5 to 49·6 octaves.

A system of reckoning which can include sound waves, wireless waves and light waves in terms of the same unit without requiring for the purpose more than five figures, seems to be deserving of serious consideration. At the same time the proposed system possesses important practical advantages over those now in use.

The following are the chief purposes for which units of wave-length, frequency or pitch are required :—

(i) The calibration of instruments (now commonly called wave-meters) by means of which each transmitter can be adjusted to the wave-length, frequency or pitch desired.

(ii) The allocation of selected wave-lengths, frequencies or pitches to particular transmitting stations.

Some wave-meters are so constructed that a switch enables the normal readings to be doubled. With such instruments, unless two scales are provided, the operator must make a mental calculation to interpret any reading on the higher scale.

If measurements of pitch are employed, no such complication arises. The two positions of the switch are marked 17 octaves and 18 octaves, or whatever it may be, and a single pointer indicates fractions of an octave on a single scale. Regarded as a "pitch-meter" the instrument reads from 17 octaves to 19 octaves on the absolute scale of pitch.

Strictly speaking, the instrument is neither a wave-meter nor a "pitch meter," but a frequency meter. The well-known relation connecting frequency and wave-length enables us, however, to graduate the scale in metres and to regard it as a wave-meter. In a similar manner, the relation between pitch and frequency defined by Equation (2) enables us to graduate the scale in octaves and to regard the instrument as a "pitch meter."

The allocation of frequencies to particular stations is usually governed by the need for avoiding interference, and the actual difference in frequency which must be provided for depends upon a number of different factors.

These factors belong to two types, the first involving an allowance of a certain fixed number of cycles per second, whilst in the second the allowance to be made is proportional to the frequency. The presence of side-bands due to the modulation in radio-telephony requires an allowance of the first type, but the other factors met with in wireless practice are usually of the second type.

It is evident that the importance of factors of the first type diminishes as the frequency increases, and that factors of this type can be neglected altogether in the case of very short waves. Under such conditions the employment of pitch rather than frequency simplifies the necessary calculations, because equal percentage differences of frequency are simply equivalent to equal increments of pitch. A change of 10 milli-octaves (0·010) in pitch is equivalent to a 0·71 per cent difference in frequency, a change of 30 milli-octaves (0·030) in pitch to a 2·1 per cent difference in frequency, and so on.

To take a practical example, suppose that it is desired to allot frequencies between 250 and 500 kilocycles per second with successive differences of 2 per cent and that the instrument available is graduated into 125 divisions, each of 2 kilocycles per second. Owing to the form in which the scale is necessarily subdivided, successive differences must be 6, 8 or 10 kilocycles per second, and it is impossible to avoid considerable departures from the desired 2 per cent difference in certain parts of the scale.

If, however, an instrument is graduated in octaves, 100 divisions will suffice and a change of pitch of 30 milli-octaves (0·030) will give the required result with absolute uniformity over the whole scale.

Recent work on wave-lengths below 100 m suggests that the use of such wave-lengths is likely to increase rapidly in the near future, and this fact lends additional weight to the above argument.

The authors would like to suggest that an absolute scale of pitch provides the most convenient method of defining frequencies over 3 000 kilocycles per second, i.e. of defining wave-lengths under 100 m, and they would urge that the method should receive the serious consideration of wireless engineers.

Discussion before the Wireless Section, 4 March, 1925.

Lieut.-Col. H. P. T. Lefroy: To estimate the practical value of the unit which the authors propose to introduce, its use should be considered from two different points of view, namely, (*a*) that of the user of radio apparatus, and (*b*) that of the designer of radio apparatus. As regards (*a*), a few years ago 100 m was about the minimum wave-length in normal use, whereas any wave-length down to about 1 m may now be used in practical radio communication. The band of frequencies available between 40 000 m and 100 m is only 1 per cent of the band available when wave-lengths down to 1 m are used, so that, for this and other well-known reasons, wave-lengths between 100 m and 1 m will be used for most of the future radio communication. It is felt by many of those who organize, control and operate radio communications that both wave-length and frequency are inconvenient units, for several reasons, particularly for wave-lengths between 100 m and 1 m: for them the new unit proposed by the authors has several advantages and should be given careful consideration. As regards (*b*), if the unit proposed by the authors is introduced, then no relation between that unit and the *CL* value of a circuit could be calculated without the use of logarithms, which would be very inconvenient, whereas, when using wave-length or frequency as units, the designer can now do such calculations without reference to tables. The authors' proposal would have more disadvantages than advantages for the designer of radio apparatus.

Captain T. G. Hodgkinson: The use of ratios to determine scale positions must appeal to all music lovers, although the audible frequencies occupy such a small portion of the known scale. The selection of one cycle per second as a unit gives lower frequencies than this negative "pitch," a point of interest to some people; engineers, however, are not so essentially concerned with frequency and wave-length as they are with the angular velocity of the periodic disturbance (I believe

that Prof. Perry first called it "speed"), and the unit "omega" (one radian per second) would make a very useful unit for the system of logarithmic division. The octave, however, has no exaggerated significance in radio work beyond the fact that it is frequently more prominent than other overtones, and the use of the common logarithm of the angular velocity rather than the logarithm to the base 2 of the frequency saves appreciable arithmetical work in the conversion of units. The use of the tenth harmonic in this way has all the advantages of the octave system outlined by the authors, and incidentally deals with the side-band type of allotment factor (by adding logarithms of consecutive whole numbers to the log of a velocity width, including the side-bands) as easily as with percentage difference factors. In the wave-meter problem it is not more difficult to add 0·3 to the mantissa of a logarithm than to add one to the characteristic in order to double the frequency of the authors' wave-meter, and the third decimal place gives a subdivision of 0·23 per cent. The logarithm of the angular velocity is an exceedingly useful figure to bear in mind, as it prevents slips in arithmetical work. The question of a name for such a logarithm does not arise, but a method of distinguishing between the common and Napierian logarithms would be to call the logarithm of 10 units of angular velocity one "Brigg," and do honour to a distinguished mathematician. Sub-audible velocities would range to 2·4 Briggs, audible velocities from 2·4 to 5, radio velocities from 5 to 9, visible light of the order of 15·5, and the velocity of the shortest gamma rays would be 20·726 Briggs.

Mr. R. V. Hansford: Although I should like to congratulate the authors on the ingenuity with which they have devised a new unit, I cannot see what advantages would follow its adoption. As regards the scale on a wave-meter, it is the type of the instrument which decides its utility, and the alteration of a scale of "wave-length" or "frequency" into an even scale of "pitch" will not improve the range or accuracy of the instrument, and to read in terms of an absolute scale of pitch would appear to be of no more value in practice than to read ordinary temperatures on an absolute scale of temperature. The authors speak of the mental calculation necessary in order to multiply by 2, but I should prefer this mental calculation to that of finding the voltage across a particular condenser when I was using 16 "pitches." The point I wish to make is that at some stage the use of frequency is essential. Therefore, why complicate matters by another unit which is merely a function of frequency? As regards the 2 per cent difference to which the authors refer towards the end of their paper, they assume that it will be desirable to calibrate from 250 to 500 kilocycles in successive differences of 2 per cent. I do not think we have any reason at present to suppose that the use of the higher frequencies will result in their allocation by percentage differences rather than arithmetical differences of kilocycles as at present. If it does so, one of the great anticipated advantages of the use of short waves will have been lost.

Major C. J. Aston: As the question of the use of wave-lengths, or cycles per second or pitch, is one which affects the user, I should like to appeal to the Press to inaugurate a discussion covering the whole world (including America, France, Germany, etc.) on this problem. It is not a matter which affects England only, or this Institution only. Previous speakers have referred to possible difficulties that will be introduced in the design of apparatus by the adoption of this system on account of the formulæ employing CL being no longer applicable. I think it will be generally agreed by designers that their skill and intelligence should be utilized for the benefit of users who are not so capable or accustomed to deal with formulæ as are designers. In my opinion the objections raised by designers are not of sufficient importance to outweigh any advantages which the proposed changes may have to the user. I would point out that with wave-lengths longer than about 300 m, i.e. with frequencies less than about 1 million per second, the absolute differences of frequency produced by telephony side-bands or required for heterodyne reception represent an appreciable percentage of the wave frequency, but that on shorter wave-lengths these side-band frequencies become of less and less importance, e.g. on 100 m wave-length a spectrum of 5 000 cycles per second is only 1/6th of 1 per cent of the wave frequency, and on 50 m wave-length it is only 1/12th of 1 per cent. It is necessary to separate channels of communication by more than these differences to allow for errors in the adjustment of apparatus and on account of the variations from the true wave-length that occur in practice. In my opinion, on wave-lengths of the order of 100 m or less the separation of channels of communication must be determined more by percentage difference than by absolute frequency difference, and any proposal which will render the use of percentage differences easier should receive most careful consideration, especially in view of the growing use of these wave-lengths at the present time. I think that Capt. Hodgkinson's alternative to the proposal made by the authors is a valuable one and I should like to see the two proposals given full publicity and their merits and objections discussed together.

Dr. R. L. Smith-Rose: One instance in which the use of a pitch scale has provided interesting results is in connection with the graphical representation of the performance of broadcasting receivers at audio frequencies. For example, the amplification curve of a stage comprising a valve with an intervalve transformer is usually plotted on a scale of uniform frequencies. On this scale the average characteristic obtained is approximately horizontal for about three-quarters of the width of the diagram. If, however, we attribute equal importance to all the notes on the pianoforte, the characteristic curve should be plotted on a scale of octaves with middle C at 256 cycles per second in the centre of the diagram. On such a scale the average transformer will be found to give a characteristic which is only straight for about one-quarter of the horizontal length of the diagram.

Mr. E. H. Shaughnessy: If we are talking of kilocycles we know that the difference between, say, 18·9 and 18·5 kilocycles is 0·4 of a kilocycle. I am not certain whether in the authors' method the difference between, say, 13 and 13·2 octaves is the same (reckon-

ing in cycles) as that between 18·7 octaves and 18·9 octaves. It is very convenient to reckon in terms of frequencies, and unless the proposed scale of octaves gives us the same easy mental facilities for calculating absolute frequency differences it does not offer any advantages over the present method.

Dr. E. T. Paris (*communicated*): The use of a logarithmic scale is almost a necessity in cases where measurements involve the consideration of wide ranges of wave-lengths and frequencies. The particular scale put forward by the authors appears to be capable of a very wide application to physical measurements, and its adoption for the calibration of wireless instruments seems to be desirable for several good reasons. There is something to be said, however, against the use of the word "pitch" as applied to the numbers obtained by taking the logarithm of the frequency to the base 2. In music and acoustics "pitch" has a well-established meaning, namely, the sensation which enables us to assign to sounds their relative positions on the musical scale. It is analogous, to some extent, to "colour" in the science of light, and to one accustomed to the use of "pitch" in the acoustical sense it would be as repugnant to speak of the "pitch" of a light wave as it would be to speak of the "colour" of a sound wave. In the generally accepted sense, in fact, "pitch" has no meaning when applied to light waves, since the ear is incapable of hearing vibrations of such high frequency. Would it not be better to find another name for the number $\log_2 (f)$, and thus avoid the confusion which is liable to arise with the acoustical meaning of "pitch"? It may be of interest to the authors to know that a somewhat similar logarithmic scale of pitch has been proposed for use in acoustical work by Harvey Fletcher (*Journal of the Franklin Institute*, 1923, vol. 196, p. 290). Fletcher defines pitch by the equation $p = 100 \log_2 (f)$. In this case the logarithm to the base 2 is not taken purely as a matter of convenience, but because the ear recognizes that notes separated by an octave are very similar sensations. Further, the factor 100 is used because the hundredth root of 2 is the average minimum interval by which two notes must be separated in order that they may be recognized by a normal ear as having different pitches. Hence a difference of unity in the pitch numbers of two notes means that they can just be discerned as giving separate pitch sensations. It will be seen that Fletcher's pitch scale has not been constructed without reference to our sense of pitch, but even then the use of the word "pitch" to describe the number P is not free from objection. The difficulty is, however, easily overcome by calling the numbers on Fletcher's scale "pitch numbers."

Lieut.-Col. K. E. Edgeworth and **Mr. G. W. N. Cobbold** (*in reply*): We should like to express our appreciation of the sympathetic reception which has been given to this paper on a controversial subject. It is natural that everyone should test the value of the proposed system by considering its application to his own work. Our view that the proposals put forward in the paper would benefit the user of wireless apparatus rather than the designer has been confirmed by the opinions expressed in the discussion.

We agree with Captain Hodgkinson that any logarithmic scale would possess the same practical advantages, but we contend that the scale suggested in the paper is more fundamental. The "user" does not have to enter into discussions involving the angular velocity of the periodic disturbance.

We think that Mr. Shaughnessy has not fully appreciated the difference between the two types of factor which govern the allotment of wave-lengths. The point is dealt with briefly in the paper and more fully by Major Aston in his remarks. A scale of pitch is not convenient for measuring definite differences of frequency such as 400 cycles, and a scale of kilocycles is equally inconvenient for measuring definite percentage differences.

We sympathize with Dr. Paris in his defence of vested interests and feel that we owe him an apology for trespass. A good deal of thought was devoted to the search for suitable terms, but nothing more suitable suggested itself.

In conclusion, we do not expect the proposed method of measurement to supersede existing methods, but we suggest that it possesses a sufficient field of usefulness to merit its adoption for particular purposes.

THE EFFECT OF WAVE DAMPING IN RADIO DIRECTION-FINDING.

By R. L. SMITH-ROSE, Ph.D., M.Sc., Associate Member.

[From the National Physical Laboratory; communicated by permission of the Radio Research Board.]

(*Paper received 3rd February, and read before the* WIRELESS SECTION *3rd June*, 1925.)

SUMMARY.

For the use of ships fitted with radio direction-finders, schemes for the provision of beacon transmitting-stations are being inaugurated in various parts of the world. In order to minimize interference it is evidently desirable that these beacons shall work on undamped or modulated undamped waves, and confidence in the accuracy of direction-finding when using these waves must accordingly be inspired in those who will make use of this application of wireless for navigation purposes. The present paper summarizes the hitherto published knowledge on the relative advantages of damped and undamped waves for accurate direction-finding, and then describes some special experiments which have been carried out in this country on this particular point. It is concluded that when direction-finding is employed at such times and under conditions which are known to produce the well-known "night effects" of variable errors in bearings and broad signal minima, these effects are equally likely on damped and undamped waves. Since the conditions under which direction-finding is accurate enough for marine navigation purposes at all times are now well known to be connected only with the distance of transmission over land and sea, it is to be inferred that the type of transmitted wave is immaterial to the accuracy, and that continuous waves, whether modulated or not, may in future be used with perfect confidence in all cases in which the damped waves from spark transmitters have given satisfactory results.

(1) PRELIMINARY.

At the present time the use of direction-finders operating upon the transmissions of radio stations is largely coming into use in its direct application as an aid to navigation. Many countries have now established collections of direction-finding stations for the use of both ships and aircraft, and in the mercantile shipping world the number of vessels which are equipped with direction-finders in addition to their ordinary wireless apparatus is increasing very rapidly. It is intended that, in part, these ship direction-finders shall operate on the ordinary coast transmitting-stations used for ship-and-shore communication, but, in addition, schemes are in being for the provision of suitable beacon transmitters, the sole function of which is to provide automatic and practically continuous transmission for the use of ships in their vicinity. In these days when the problem of restricting interference is one of the most acute in the art of radio communication, the possibility of these beacons employing "spark" transmitters is obviously viewed with some alarm. Yet among some of those responsible for navigation by wireless there is still a lack of confidence in the use of continuous waves, whether modulated or otherwise, as against damped waves, on account of the greater liability to error when employing the former type.

It will be advantageous, therefore, to examine all the available evidence on the use of continuous waves in direction-finding in order to understand if the reputed greater liability to errors is well-founded or otherwise. The subject was recently discussed briefly before the Wireless Section of this Institution,* but, as one speaker then stated, the matter was left in an unsatisfactory state, and the author will attempt in what follows to make his views on the subject quite clear.

(2) SUMMARY OF PREVIOUS KNOWLEDGE.

A. H. Taylor † appears to have been the first to publish, in 1919, systematic observations taken on both damped and continuous waves at Washington, U.S.A. Using continuous waves of length from 4·0 to 16·7 km, the variations recorded range from a few degrees in the daytime up to nearly 90° at night. It appeared to Taylor that, in general, the variations were greater on the longer than on the shorter waves, except where the transmission is over a comparatively short distance. For example, Annapolis (16·7 km, continuous waves) observed at Washington at a distance of 35 miles, practically over land, showed an extreme variation of 10°, whereas New Brunswick (13·6 km, continuous waves) at a distance of 175 miles showed nearly 90° variation. The only observations on spark transmissions referred to were made on the much shorter wave-lengths of 0·9 to 1·5 km, and in the case of Brooklyn on the latter wave-length a variation of 30° was recorded for a distance of transmission of about 250 miles, almost entirely over land. In view of the object of the present discussion it is considered interesting here to quote the concluding sentence of Taylor's paper. "The writer has no available data on continuous short-wave stations, but ventures to suggest that there is far more likelihood of serious deviations in the apparent bearings of such stations occurring than in the case of spark stations on similar wave-lengths."

* *Journal I.E.E.*, 1924, vol. 62, p. 701.

† A. H. TAYLOR: "Variation in Direction of Propagation of Long Electromagnetic Waves," Bureau of Standards, Scientific Paper No. 353, 1919.

In a paper summarizing a great deal of experience in direction-finding, Round * in 1920 mentioned the existence of variations at night, ranging up to 7° on "spark" signals and exceeding 30° on continuous-wave signals. Expression was given to the lack of evidence at that time showing any increase in the variation with wave-length, and the discussion on the paper indicated the somewhat hazy state of knowledge of these variable errors which then prevailed.

G. M. Wright † observed in 1920 that, in addition to "night effect" being more marked with undamped than with damped waves, its existence is indicated much more frequently in the latter case by the broadness of the signal minimum upon which the bearing is observed. The simultaneous occurrence of sharp minima and inaccurate bearings was considered to be very rare on damped-wave transmissions.

Further observations were published in 1920 by Kinsley and Sobey,‡ who made measurements on wave-lengths of 0·96 to 5·7 km from "spark" stations and 4·9 to 17·3 km on continuous waves. Variations in apparent bearings ranging up to 50° are recorded for distances of transmission of from 40 to 7 500 miles. The authors' experience indicated that undamped waves of great length show these variable effects much more frequently than damped waves of shorter length; but since the distance of transmission is usually very much greater in the former than in the latter case they express their conclusions on this matter as follows: "There does not seem to be any reason to believe that the short-wave sparks may not, under favourable conditions, show distortion (i.e. variations) of the same magnitude as that given by other types of transmitters." Several examples on both damped and undamped waves of failure to detect any signal minimum during a rotation of the direction-finding coil through 360° at certain periods of night variations, are given in the paper.

Pickard,§ in 1922, published some results taken on various American and two European stations, a feature of the results being that the bearings on the European stations at Otter Cliffs, Maine, U.S.A., showed a smaller average variation than those on the San Diego station. For example, the average variation of both day and night readings obtained during the month of August, 1921, was 2·1° on New Brunswick, 3·8° on Nauen, 4·2° on Bordeaux, 4·3° on Glace Bay, and 10·6° on San Diego. From the curves given in the paper it is seen that the average variation at night ranged up to about 12° for Nauen and Bordeaux, so that the individual variations must have been quite considerable. The chief feature of the difference in paths of transmissions from San Diego and from Europe to Otter Cliffs is that the former is entirely over land, whereas the latter is mostly over sea, except for the grazing incidence of the waves down the Atlantic coast of America.

§ G. W. Pickard: "The Direction and Intensity of Waves from European Radiotelegraphic Stations," *Proceedings of the Institute of Radio Engineers*, 1922, vol. 10, p. 161.

Some observations made in France by Mesny * over a considerable period were published in 1922. These records showed that when using undamped waves of lengths 10 to 25 km the variations in apparent bearings at night ranged up to 90° for distances of transmission of 200 to 600 miles over land. No systematic error was evident in these cases, but when making similar observations on one of the American transmitting stations at a distance of about 4 000 miles, mostly over sea, a systematic error of 5° was found and the variations about this mean were confined to about 2·5°. Observations carried out on "spark" transmitting stations using damped waves of length 600 to 1 000 m resulted in only comparatively small errors of 10° or 15° at ranges of transmission of not less than 30 miles over land. In a large number of these cases it was found difficult to make any observation at all owing to the extremely flat minimum encountered at night. In the paper referred to, Mesny expresses the opinion that the difference in observed effects as described above was not due to the damping of the waves but to the difference in wave-lengths.

From the above brief résumé of previously published data it will be seen that there has hitherto been little opportunity of making any comparison between the relative effects of damped and undamped waves upon the errors and variations experienced on radio direction-finders. The only comparisons that have been carried out have been made between damped waves of short length (below 1·5 km) at short or medium ranges and undamped waves of great length (greater than 5·0 km) at comparatively long ranges, and at least two sets of experimenters have expressed the opinion that it was the difference in wave-length rather than the damping which was responsible for the varying results obtained. Since it is now known that the distance and also the nature of the path of transmission, whether sea or land, may affect the results, and also that, until recently, the shape of the transmitting aerial was suspected to have some influence,† it was evidently unfair to compare results obtained on damped waves from one station with those obtained on undamped waves from another station. For a strict comparison to be made it is essential for the waves to be as nearly as possible of the same length and to be emitted from the same aerial, and for the change from damped to undamped waves to be made as quickly as possible when observations are being carried out.

In his textbook published in 1922, Keen ‡ repeats the experience described by Wright that indefinite and distorted minima are more pronounced in connection with continuous waves than with damped waves, and that the presence of night-effect conditions can usually be recognized in the case of spark signals, since a sharp displaced minimum is exceedingly rare. The statement is made without any qualification as to the effects of wave-length, distance and nature of path of transmission, and is evidently meant to convey the

‡ R. Keen: "Direction and Position Finding," 1922, p. 192.

impression that in the case of damped-wave transmission some warning of the existence of "night effect" with its possible varying errors is conveyed to the operator of the direction-finder, whereas in the case of undamped waves the minima are usually, if not always, quite sharp and serious errors in bearing may pass unnoticed. Keen has also pointed out * that such a result is to be expected if the theory of night errors put forward by T. L. Eckersley † is correct. It will be generally admitted, however, that it is experimental evidence, rather than deductions from a by no means universally accepted theory, which is required to settle a point of such vital interest to the future of wireless direction-finding.

(3) Recent Experiments.

In a paper ‡ published in 1922 the author described experiments which showed how errors might arise in the use of direction-finders on continuous-wave transmissions when the field from the local oscillator used for heterodyne purposes was allowed to interlink the receiving loop. The difficulties of adequately screening a valve oscillator were emphasized and the details of the design of a suitable screened oscillator were given. Oscillators of this type were employed at a number of direction-finding stations situated in Great Britain, engaged under the auspices of the Radio Research Board in the daily observation of the apparent bearings of many European transmitting stations. A large mass of data was collected during the years 1921–24, and the results of its analysis are being published in a series of official reports.*

(*a*) *Transmissions on long waves* (2 *to* 9 *km*).—During the first year of working the observations were confined to damped-wave transmission, whereas during the second year about 80 per cent of the total observations were made on undamped waves. The maximum variations recorded at each observing station were of the same order during the two years and ranged from 50° to 90°, the undamped-wave observations during the second year showing no marked difference from the damped-wave observations of the same or the previous year.

Among the relatively large mass of observations analysed in these reports, the only two transmitting stations which gave conditions approximating to the ideals mentioned above were Clifden and Karlsborg, and in Table 1 is given a summary of the whole year's observations obtained on these stations. The difference in wave-length in the case of the Karlsborg transmissions is known not to be responsible for any marked difference in the effects observed. It is seen from the table that although in some cases, both by day and by night, the extreme errors appear to be slightly

greater on undamped waves, the reverse is also true in other instances; and, particularly at night, the proportion of the errors is less on undamped than on damped waves. The actual differences tabulated are probably not significant and the deduction is therefore made that, provided the necessary precautions are taken with the direction-finding receiving apparatus as previously described, no difference in the ordinary night variations is experienced with the use of either damped or undamped waves of lengths within the range of 2 to 6 km. It may also be pointed out that in the case of the transmissions from Karlsborg to Aberdeen and Newcastle more than three-quarters of the path of transmission is over sea, whereas from the Clifden transmitting station the major portion of the path was over land.

(*b*) *Transmission on shorter waves* (750 *to* 1 800 *m*).—Between November 1923 and March 1924 a series of experiments was conducted, in which probably the closest possible approach to the ideal conditions mentioned in Section (2) was realized. For this purpose the transmitting station of the National Physical Laboratory, Teddington, was utilized, special signals being sent in turn on damped waves, interrupted continuous waves and continuous waves. The three types of transmission followed each other at regular intervals of two or three minutes, the whole cycle of transmissions being repeated every 10 minutes. Two direction-finding stations were employed at Orford and Slough respectively, and the experiments took the form of a series of simultaneous observations at the two stations over continuous periods of 24 hours at a time.

At the Slough station, distant only 11·5 miles from Teddington, no difference whatever could be detected in the bearings observed on either type of transmission by day or night. The maximum error in bearing observed throughout the whole series of tests was less than 2°, the great majority of the readings being correct to within 1°.

At Orford, distant 93 miles from Teddington, the observed bearings showed the usual effects associated with daylight and darkness. A summary of the results obtained in these tests is given in Table 2, in which no distinction is made between the day and night portions of the 24 hours.

By making an arbitrary division of the day and night periods at one hour after sunrise and one hour before sunset, the day observations are found to give a maximum error in bearing of less than 3°, and all the larger errors recorded above occurred during the night. It will be seen from the table that there is no obvious difference in the order of the variations experienced with either of the types of wave employed. In the last column is recorded the proportion of cases in which the signal minimum was so broad that no observation of bearing could be made. This proportion is seen to be quite an appreciable fraction of the total observations, particularly when it is remembered that the figure is considerably "diluted" by the daylight readings. While the exact percentage of readings giving such flat signal minima was found to be very variable in the different tests, it will be noted that there is a tendency for the continuous-wave transmission to give a maximum proportion and for the interrupted continuous waves to give a minimum proportion of such readings.

The above tests from Teddington to Orford were carried out at a distance over land for which previous experience has shown direction-finding to be of little use at night, on account of the variable errors and the ill-defined signal minima obtained. A consideration of all the results in Table 2, giving due weight to them in accordance with the number of complete 24-hour tests worked, tends to the deduction that the above differences in the results obtained are not very significant; the general conclusion being that all the usual types of night effect in direction-finding are equally likely to occur with either damped waves and with undamped waves, whether interrupted or not. The actual figures

TABLE 2.

Summary of Direction-Finding Observations made at Orford on Various Transmissions from Teddington.

(Distance = 93 miles; true bearing = 240·6°.)

Type of transmission and wave-length (m) *	Number of 24-hour periods worked	Total number of observations	Observed bearings: Extreme variation	Observed bearings: Percentage more than 2° from mean	Observed bearings: Percentage more than 5° from mean	Percentage of flat minima recorded
			deg.

* C.W. = continuous waves; I.C.W. = interrupted continuous waves.
† In a subsequent test on this type of transmission the flat minima recorded were less than 15 per cent.

indicate that the type of effect known generally as broad or flat minimum is more common with undamped than with damped waves, but on account of the warning it gives to the operator this effect is not harmful in the application of direction-finding to navigation problems.

(4) CONCLUSIONS.

From careful, systematic observations carried out on various wave-lengths from 750 to 6 000 m it is concluded that the liability of wireless direction-finders to the type of errors known as "night effect" is equally great with damped and undamped waves. The special experiments were carried out with transmissions made directly over land, when it is common experience that these night-effects occur for ranges exceeding about 30 miles. Since, however, it has

already been shown * that when the path of transmission is entirely over sea and free from land and coastline effects, direction-finding with damped waves is accurate enough for most navigation purposes at distances up to 80–100 miles, it is inferred that equal reliability would be obtained with undamped waves. This is in direct confirmation of some experiments † carried out by the United States Lighthouse Service with radio beacons provided with modulated continuous-wave transmitters for the use of direction-finders on board ship. Comparative tests carried out with these and with the ordinary spark beacon transmitter showed that at various distances up to 132 miles over sea the accuracies were practically identical in each case, both by day and by night. The faith of the authorities in their results is exemplified by the fact that they are already introducing the modulated continuous-wave transmitters into their beacon stations.

Discussion before the Wireless Section, 3 June, 1925.

Commander J. A. Slee: One specific purpose for which direction-finding is used is for the navigation of ships, and I wish to make a few remarks on this aspect of the matter. Either the ship can carry a direction-finder and take bearings of transmissions from known, fixed points, or the ship can do the transmitting and the direction-finder can be placed on land. In the present state of affairs there are a great many more ships with direction-finders than there are direction-finding stations on shore. At present the usual method —and I think from the seaman's point of view by far the best method—is for the ship to carry the direction-finder, so that when it comes to the navigation of ships the problem is to obtain accurate bearings in a ship from a fixed point. Experience shows that for most kinds of direction-finding, if the transmitting station, which is fixed, is any considerable distance inland, the bearings are poor. One must remember the conditions of navigation, however. It is not an academic study of the problems of direction-finding; an accurate bearing of a fixed point is what is required. The things which seamen are accustomed to deal with are headlands, lighthouses or similar fixed points on the coast, and they do not want bearings at long distances. I think it is safe to say that reliable bearings at 100 miles is the maximum requirement, and that in the great majority of cases 50 miles is quite enough. Thus the problem of direction-finding as applied to the navigation of ships is one of fairly short-distance work. The next point is to select transmitting stations which are suitable to the apparatus, viz. fairly short-wave stations situated on the coast—usually the 600-m stations used for communication with ships. The vast bulk of experience has been gained with these stations. It has been found that, due to the position of the land round the station, the existing coast stations have only comparatively small arcs in which bearings good enough for navigation can be taken. A demand has therefore arisen, and has just begun to be supplied, for special stations other than these stations for the purpose of assisting ships. The name which is being attached to this class of station in England is the "beacon" station. At present a wave-length of 1 000 m is being used, so we can state that from the point of view of navigation of ships a knowledge of the behaviour over moderate distances (all over water) of waves from 600 to 1 000 m is what is chiefly required. When ordinary spark transmitters are used their outstanding disadvantage is the amount of interference which they cause to other wireless services, and it is undoubtedly the object and the hope of everybody concerned with wireless to get that interference reduced. Against this it has been found that the reliability of the bearings taken from a spark station is of a high order. There is almost always a period between darkness and daylight when the bearings taken in a ship go wrong. The chances of error due to a bearing being taken during that period are small, because everybody knows the trouble and avoids it. If a bearing has to be used, it is used with great caution during those times. Once it is thoroughly dark it is very uncommon for the spark bearings to go wrong, but if they do so there is nearly always a great deterioration in the sharpness of the minima obtained, which gives warning of the temporary unreliability of the bearings. Thus the spark system has forced itself into a position of reliability and confidence among those concerned in the use of direction-finding for navigation. In order to get away from the interference difficulty, the problem of I.C.W. has been attacked, and as far as possible experiments have been made; but with ships which are actually at sea and using their direction-finders for navigation purposes the opportunity for academic experiment is not very great. The tendency is to show that at the moderate distances over which a ship requires bearings, I.C.W. behaves just the same as spark waves do. It is no worse and no less reliable, and the interference which it causes is undoubtedly considerably less. Therefore everybody concerned with the navigation of ships is perfectly content with the substitution of I.C.W. for spark. There remains the case of pure C.W. There is no very great amount of experience available, but what there is can be summarized in this way. For direction-finding purposes the ordinary form of direction-finder uses the familiar figure-of-eight diagram, but if that diagram is used during the hours of darkness it seems to be indisputable that pure C.W. bearings are very prone to wander. If the equally well-known heart-shaped diagram is used, then that wandering is a very great deal less, even if it does not entirely disappear. There remains the fact, however, that in ordinary practice it is very difficult in an iron ship, if not impossible, to get the polar curve of the heart-shaped diagram truly symmetrical. The result is that the two parts of the curve adjacent to the zero point are not alike, and the method of observa-

tion (which consists of taking two points of equal signal strength) will fail because those two points are not equally distant from the zero point, a resultant error of about 3 or 4 degrees remaining. I do not think it would be right to put it any lower than 3 degrees or higher than 5 degrees. The navigators of big ships nowadays have got into the habit of working to a higher degree of precision than this, and as a result I think I am right in saying that those using direction-finders for the navigation of ships at sea, although they would raise no objection to the introduction of I.C W. instead of spark for beacons, would all deplore the use of pure C.W. for beacons and for navigation as opposed to I.C.W. The I.C.W. stations at moderate ranges are quite satisfactory. At the longer ranges there is some evidence of I.C.W. wandering, but one cannot say that it is more so than in the case of spark, and for the case of ship navigation these longer ranges are not important. To put the matter in a nutshell, I think that, so far as the navigation of ships is concerned, the use of I.C.W. is perfectly suitable and satisfactory, and the amount of interference it is likely to cause to other services is not great. I do not think there is such a thing as a direction-finder at sea without a powerful amplifier attached to it, so the amount of power required to allow of accurate bearings being obtained at moderate distances (up to, say, 50 miles) is not very great. For instance, Trinity House has just started an experimental beacon station at Round Island, Scillies. First-class bearings at that place have been obtained at distances up to 100 miles. There is no question that that station is much more powerful than is necessary, and it has been blamed for interference, but it is clear that the power can be very considerably reduced.* At any rate, as far as Great Britain is concerned I think I am justified in saying that a station such as Round Island is the most powerful form of beacon station that can be wanted, and far less powerful stations will do all that is necessary further up the Channel and in narrower waters.

Dr. S. H. Long: The author has raised a very important question relative to direction-finding. It has long been the idea of many people employed on direction-finding work that C.W. and I.C.W. were of little use for such work. One can readily appreciate the advantages of C.W. or I.C.W. over spark if they could be used for direction-finding. This is especially the case in the present rapid advancement and progress in the art of direction-finding at sea, and in the development of radio-beacon stations in congested waters. I have been privileged to carry out a regular development of a system of direction-finding which has proved itself specially suitable for C.W. and I.C.W. work. Comparisons have been made with results on spark stations on wave-lengths used in mercantile radio communication, i.e. on wave-lengths of from about 450 m to 1 250 m. These tests have been carried out on transmission over both land and sea up to about 150 miles, and the general conclusions reached are that (*a*) the reliability of bearings on C.W. and I.C.W. is equal to that on spark; and (*b*) the working on C.W. or I.C.W. is preferable to and easier than that on spark, owing to the great selectivity and consequent lack of or diminution of jamming. Bearings can be taken on C.W. under conditions which entirely prohibit the taking of spark bearings. In regard to night effect, the results obtained at sea show that C.W. and I.C.W. are quite as reliable as spark by night. It has frequently been stated, as mentioned in the paper, that spark is more reliable than C.W., as the operator knows when "night-effect" is present, owing to the "woolly" indistinct minima. Our experience proves that this is not sound and that the trouble experienced is due not to the nature of the transmitted wave but to the type of reception used. In the system we have been developing, a compensating vertical aerial for sharpening up the minima in conjunction with a single rotating frame aerial is used. This compensating device operates on the set by means of a variable coupling, which changes with the angle of incidence of the wave-front on the receiver frame. With a vertical wave-front the coupling is extremely loose. When "night effect" is present the following phenomena are noticed: (1) The coupling between the rotating frame and the compensating vertical has to be tightened; (2) the bearings on C.W. can always be made sharp by the use of the coupling to the vertical aerial; (3) the C.W. bearings are very sharp when correct adjustment of coupling with the compensating vertical aerial is used, but these bearings in a few seconds tend to wander rapidly, i.e. if the true bearing is, say, 120°, in the course of 15 to 20 seconds one gets bearings of, say, 110°, 115°, 120° and 130°; and (4) the tightness of the coupling between the compensating vertical aerial and the rotating frame is an unfailing indication to the operator as to the reliability of bearings. Thus we see that although the direction-finding set cannot compensate for the refraction or reflection of the incoming wave, it at once indicates whether this refraction or reflection is present and warns the operator as to the correctness of the bearing read. This variation of coupling between compensating vertical aerial and rotating frame aerial when "night effect" is present seems to indicate a rapid changing in the slope of the wave-front relative to the rotating frame. This has been proved by using, in lieu of a rotating frame on a vertical axis and a compensating vertical aerial, a rotating frame on an axis which is also capable of rotation through about 60 degrees to the vertical. The greatest importance in the reception of C.W. lies not only in the choice of oscillator used but also in the method by which the oscillator is coupled into the receiving direction-finding system. Any system in which a secondary effect of the oscillator can occur is liable to produce errors, and the simplest system is that of a single rotating frame in which no secondary effects are possible. If more than one frame is used with the oscillator in the electrical centre of the frame and receiver, then complications are liable to arise, with consequent unreliability of bearings. Can the author give any information regarding the reliability of direction-finding on C.W., I.C.W. or spark systems of, say, 50 to 250 m wave-length? It

* This has now been done. At the moment good bearings are obtained at 40 to 50 miles.

is obvious that these are the wave-lengths to which great attention must be paid in the near future.

Mr. R. Keen : The paper summarizes very well the situation regarding the comparative reliability of spark, C.W. and modulated C.W., and it certainly seems that we are approaching the point at which we can say that we know roughly the limitations of the three systems of transmission. The evidence is still, however, a little conflicting. The author states that the only comparisons which have been made in the past regarding C.W. and spark have been made with damped waves at short distances and on short wave-lengths, as against C.W. on long waves and at great distances. Perhaps these are the only tests which have been published, but we must not forget the war experiences. The author refers to Round's paper, and in connection with the discussion on that paper he says that the knowledge of these variable errors seemed to be rather hazy at the time. Possibly that was the case, but the facts remain that many thousands —probably hundreds of thousands—of bearings were taken by very expert operators down our East Coast during the years 1915 to 1918, on both spark and C.W. stations from 1 800 m upwards and at distances of about 200 miles, mostly over sea. It is unfortunate that the whole of these readings could not have been analysed, but that was impossible at the time and we are obliged to rely on the impressions of those engaged on the work and those impressions were that the C.W. errors were very appreciably greater than the spark errors. What appears to me to be the most important point in the paper is contained in the concluding paragraph where the author infers that at distances up to 80 or 100 miles over sea, C.W. will be as reliable as spark. If this means that modulated C.W. is as reliable as spark, well and good, but in the summary which prefaces the paper pure C.W. is also included with modulated C.W. as being a type of transmission which can be used with perfect confidence wherever spark gives satisfactory results. Now, the opening words of the paper state that the purpose of all this work has been to get down to a reliable system of beacon working for ships and it seems to me that there is only one way in which we can ever find this out, namely by taking all our test-bearings from an iron ship at sea on beacon stations on shore of the power and type which will be used commercially. Such tests would prove costly but the results would be a final answer to all discussion on the subject. It is of the greatest interest to note that such tests have been carried out in America and that the results show that spark and modulated C.W. have approximately the same degree of reliability, but in view of the commercial interests involved and the extreme importance of the whole subject it seems not unreasonable to hope that the Radio Research Board will carry out some similar tests for purposes of confirmation. At the top of col. 2 on page 923 is a remark which is not quite clear to me. It is mentioned that the power necessary for a beacon station for the use of ships with crystal reception would have to be fairly high, but surely any ship having a direction-finder would also have valve reception. The author refers to my book and I agree with his remarks. My statement that errors on spark transmission nearly always give warning of their existence by indefinite minima, whilst C.W. bearings may be 30 or 40 degrees out and still have crisp minima, is to be taken generally as indicating the characteristics of the two types of transmission and may occur no matter what the wave-length or type of path may be. The author is a little sceptical regarding the Eckersley theory of the cause of night-effect errors, but it still remains the only theory which accounts in such a striking way for practically all the phenomena met with in direction-finding work. However, again I agree with the author that it is experimental evidence which is required, and this point cannot be emphasized too strongly. Although the information supplied by the Radio Research Board during the past two years has been extraordinarily interesting and valuable, I feel that this question of the reliability of C.W. and modulated C.W. beacons for ship direction-finding work can only be settled by further tests under working conditions, since direction-finding on a shore station and in a ship are totally different problems.

Major B. Binyon : In Section (1) of the paper the author refers to the serious interference which, in his opinion, would be incurred by the use of beacon stations operating on the spark system. I think, however, he overstates the case since such stations would not operate continuously, but only in thick weather, and then for a period of only 1 minute in every 10. Furthermore, the power employed by such transmitters need rarely exceed ½ kW, since the receivers used in conjunction with the ships' direction-finder sets would be highly sensitive, of the multi-valve type, and not crystal detectors as suggested in the paper. I am in agreement with Commander Slee that I.C.W. might be employed for beacon station work, though the plant is likely to be more costly. In considering the progress which will occur in marine development it is natural to suppose that the transition from the spark system to the C.W. system will be by the intermediate use of I.C.W. This transition, for financial reasons, must necessarily be gradual and it is therefore important, if we are to see progress in this direction, that there should be no technical reason why C.W. or I.C.W. cannot be exclusively used on board ship. It is most important, therefore, bearing in mind that ships may wish to take direction-finding bearings on one another—and this subject is altogether ignored in the paper—that the question of whether or no reliable bearings on C.W. can be obtained should be conclusively proved. In the author's conclusions he says: "Since, however, it has already been shown that when the path of transmission is entirely over sea and free from land and coastline effects, direction-finding with damped waves is accurate enough for most navigation purposes at distances up to 80–100 miles, it is inferred that equal reliability would be obtained with undamped waves." I do not think that this has been by any means proved by the author, nor that an inference of this character, on a subject so important, is justifiable. We have already experienced considerable difficulty in persuading the average mariner that direction-finding

on the damped-wave system is sufficiently accurate for navigation at sea, and I should be sorry if the progress of direction-finding were retarded by the establishment of C.W. beacons, unless it were conclusively proved that the same order of accuracy could be obtained therefrom as with the spark system. It is, however, admitted, as Commander Slee has stated, that reasonable accuracy may be expected on I.C.W. In connection with the wave-lengths on which experiments have been conducted and referred to in Table 2, it is unfortunate that these experiments could not have been made on the wave-lengths (spark, I.C.W. and C.W.) used by ships at sea, though one of these, viz. 1 000 m, is the wave-length proposed for use by beacon stations.

Mr. R. H. Barfield : When studying the paper I came to the conclusion that the lively controversy which existed before it was written was efficiently disposed of by the 10 000 (or so) observations contained in it, but I was apparently mistaken. In comparison with the mass of evidence contained in the paper my own experience is almost negligible, but I can testify that I have spent many hours by day and night taking observations of both damped and undamped waves, and I have never noticed any difference in the two classes as regards liability to errors.

Lieut.-Col. H. P. T. Lefroy : In this discussion, which deals with present methods of direction-finding, we should not lose sight of the fact that such methods are probably obsolescent and may be replaced by rotary beacons, with which the errors under discussion would not occur. Such beacons are analogous to rotating-beam lighthouses. Their range might be 50 miles, and I think, from what Commander Slee has said, that this will be sufficient. By arranging for one complete rotation in 72 seconds, and using a 1/10th second stop-watch in conjunction with the receiver, it should be possible to obtain the bearing of the transmitting beacon accurate to half a degree, and there should be no errors except those due to faulty observation. For various reasons, the radiation would be on wave-lengths shorter than 100 m, and I.C.W. would probably be used. As regards the ordinary systems in use at present, if I.C.W. is going to be used it is worth considering whether interruption could not be applied at the receiver instead of at the transmitter; in the latter case signals are heard as I.C.W. by those who are using them and also by those to whom they are causing interference, whilst in the former case they are heard as I.C.W. by those who are using them, but as C.W. by those who are not using a local interrupter with their receiver, so that less interference is caused. With properly designed apparatus the range, for a given C.W. input, is probably not less when interrupting at the receiver than when interrupting at the transmitter.

Admiral of the Fleet Sir H. B. Jackson : The discussion appears to have evinced the fact that spark and I.C.W. are equally to be depended upon. There is a certain amount of difference of opinion about C.W., but this may be due to the type of receiving station used. The author has carried out his experiments at well-tested stations where there were no local errors of any sort to be expected; whereas with those carried out in iron ships there are errors which are inherent in the station itself. Possibly the matter may be investigated by the Radio Research Board. Unfortunately the Board have not a ship at their disposal, but it is possible that they may think it necessary to obtain one for this purpose. At any rate I shall bring the matter to their notice.

Dr. R. L. Smith-Rose (*in reply*) : It is evident from the discussion that although a position of equality has been won for interrupted continuous-wave and damped wave transmission in wireless direction-finding, the question of its reliability in the case of continuous-wave transmission is still debatable. In regard to the latter case I must say that I see no reason to depart from the conclusions stated in the paper, for no satisfactory evidence has, in my opinion, been brought forward against them. Dr. Long's experience directly confirms my results and he is apparently satisfied as to the reliability of continuous-wave working over sea. Mr. Keen, on the other hand, has brought forward the only real evidence which has ever confronted me as to the greater liability to error of C.W. direction-finding, viz. that obtained during the years 1915–18. I would suggest, however, that the results of the investigations which it has been my privilege to conduct during the past five years are superior both in quantity and quality to those obtained during the above-mentioned period. They were begun with all the benefits of the experience of the preceding years, and were systematically planned and carried out under conditions free from the stress which necessarily accompanied the work done during the war. Furthermore, all the results obtained have been very carefully examined and co-ordinated and are now placed on record.

The real point which now remains at issue, however, has been made very clear by Commander Slee, Major Binyon and Mr. Keen. It is that although I have inferred that continuous-wave direction-finding is accurate over sea for distances up to 100 miles, there is no direct evidence for it; and the confidence of the mariner will not be obtained until the point has been proved. Owing to the very few ships fitted with undamped-wave transmitters no results for oversea working on C.W. were obtained during the experiments carried out at the Orford direction-finding station. The matter will obviously require the arrangement and carrying out of special experiments. It would appear to be desirable to make these experiments of a two-way nature, using one direction-finder on shore and one on a ship at sea; the ship and shore stations being also equipped with both spark and C.W. transmitters. Major Binyon has mentioned the additional desirability of carrying out tests between two ships. Constant tests would need to be carried out over a considerable period and the expense would naturally not be small.

Pending the carrying-out of such experiments it is to be hoped that the direction-finding services will be converted to I.C.W. working as soon as practicable. In this connection it is interesting to observe that confirmation of the reliability of modulated C.W. for direction-finding is afforded by the fact that the French authorities converted the radio-beacon at Cape Gris-Nez

from spark to modulated continuous-wave transmission as early as 1923.* In the paper referred to, it is stated that the results are quite as accurate as those obtained with damped-wave transmissions, and the remaining stations of the French radio-beacon service will shortly be converted in a similar manner.

Apart from the effect of wave-damping, Commander Slee mentions the variations in bearings observed when the path of the waves is along a coast or over land. I have recently become very interested in this phase of direction-finding, for although the experimental evidence is rapidly accumulating and is undeniable, the theoretical side of the subject is in a very unsatisfactory position. It is hoped to inaugurate some experiments to investigate this particular point in the near future. I have never experienced the twilight effect mentioned by Commander Slee, according to which the bearings are apt to be more unreliable in the neighbourhood of sunset than when total darkness prevails.

Dr. Long states that he uses a compensating vertical aerial for sharpening up the minimum, and also that the extent of the coupling of this aerial to the main receiving coil provides a means of detecting a change in the slope of the wave-front. Without practical experience of this particular arrangement I am loth to criticize; but I should like to draw attention to some recent experiments, the results of which show that owing to the

* A. Blondel: "Acoustic Selection in Radiogoniometry," *Comptes Rendus*, 1925, vol. 180, p. 1000.

high effective conductivity of the earth, the directions of the resultant electric and magnetic forces at the earth's surface due to a wave arriving at any angle of incidence are not seriously different from those obtained in the day-time with a single wave propagated horizontally.* On wave-lengths above 2 600 m the electric force never departs from the vertical by much more than 1°, and the magnetic force is always horizontal to within the same limit. In reply to Dr. Long's inquiry I regret that we have as yet no results to communicate as to direction-finding work on wave-lengths of 250 m and below.

I have to thank Mr. Keen and Major Binyon for drawing my attention to the paragraph referring to the use of crystal detectors. This was inserted in error and has now been deleted.

Colonel Lefroy has given us a reminder that there are systems of rotary beacon transmitters from which bearings may be obtained, and which may eventually supersede directional reception methods. At the present time I feel that the experimental evidence supporting the statement that these beacons should have no errors is somewhat small. It can be shown theoretically that one type of rotary beacon is liable to give errors under certain conditions, and it remains for the results of experiments to show how serious such errors may be.

INSTITUTION NOTES.

Scholarships.

The following Scholarships have been awarded by the Council for 1925–1926:—

David Hughes Scholarship (value £50).

G. N. Peel, B.Sc. (Armstrong College, Newcastle-on-Tyne).

Salomons Scholarships (value £50 each).

R. O. Carter [City and Guilds (Engineering) College].
H. S. Leman (East London College).

National Certificates and Diplomas in Electrical Engineering.

The following schools have been approved under the scheme drawn up by the Board of Education and the Institution:—

Approved for Higher Grade Certificates (Advanced Part-time Course).

Leeds Central Technical School.
Leigh Municipal Technical School, Lancs.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 July–25 August, 1925:—

REPORT ON MEASUREMENTS MADE ON SIGNAL STRENGTH AT GREAT DISTANCES DURING 1922 AND 1923 BY AN EXPEDITION SENT TO AUSTRALIA.

By Captain H. J. ROUND, M.C., Member, T. L. ECKERSLEY, K. TREMELLEN and F. C. LUNNON, of Messrs. Marconi's Wireless Telegraph Co., Ltd.

(*Paper received 27th November, 1924, and read before the* WIRELESS SECTION *6th May,* 1925.)

PREFACE.

(By Captain H. J. Round, M.C.)

The first accurate wireless measurements of signal strength were made by Duddell and Taylor in 1905, and from 1909 to 1913 Austin and Cohen carried out a series of experiments over long distances from which they deduced their well-known formula.

In 1911-1912 the author and Mr. Tremellen carried out a fairly extensive series of measurements on daily and annual variations of high-power station signals at Chelmsford, and afterwards on various voyages. Practically all these tests were carried out with spark transmission.

In 1921 Vallauri published the first results on the use of the comparison method of measuring signals (originally suggested and used by Eccles for spark work).

The author, with Mr. Lunnon, just previous to this publication by Vallauri, had started developing a comparison method for measuring signals, differing in some particulars from that of Vallauri. Vallauri used two frame aerials at right angles, one pointed in the direction of signals and the other at right angles. The real signals on the one aerial were then compared by ear with artificial signals induced on the other one. We, however, used an artificial aerial instead of the aerial at right angles to the signal aerial.

Both methods have the serious fault that atmospherics are not of the same strength on the two systems, and Tremellen later on developed the "chip in" method, where the end of a message or a pause is waited for and, immediately transmission ceases, the artificial signal is induced in the real aerial. Whenever alternate dashes and spaces can be obtained from the transmitter it is of advantage.

A large number of preliminary experiments were carried out by Eckersley, Lunnon and Tremellen, to determine (*a*) errors of the instruments and (*b*) effective heights of aerials, and to get general experience in the use of the apparatus.

Continuous observations were then taken on various stations, first at Chelmsford (Broomfield), and then at various places in Great Britain.

Through the support of Mr. Alexanderson, a technical commission consisting of Mr. Beverage and Mr. Rust was sent to Brazil completely equipped with the measuring gear, to gather accurate data on European and American signals there. Here the first use of the instruments was made to determine the strength of atmospherics, the strength being defined as the E.M.F. required to be induced in the aerial in order to enable signals to be read at 20 words per minute.

This may be of questionable scientific value as a measurement, but is undoubtedly of great practical value, as it enables one to indicate how much stronger the transmitter must be to give a commercial service.

A further expedition to South Africa under Mr. L. D. Hill, again equipped with measuring gear, gave additional data.

We had, however, planned a much more extensive expedition which would give sufficient data on long waves to enable us to design stations for communication between any two places or to indicate whether such communication was beyond commercial possibilities.

Through the strong support of Mr. Godfrey Isaacs this bigger expedition was rendered possible, and Mr. Tremellen, accompanied by Mr. Allnutt, started on the 28th January, 1922, on the S.S. "Dorset," on a voyage to New Zealand, via Panama. The ship was fitted with the latest measuring apparatus and a large amount of auxiliary apparatus for direction-finding, etc. Our thanks are due to the owners, captain and officers of the S.S. "Dorset" of the Federal Shire Line for their invaluable aid during all these tests.

The gear was unshipped at New Zealand and sent to Australia, where the experiments were continued at Sydney, Melbourne (Koo-Wee-Rup) and Perth. The return voyage on the S.S. "Boonah" of the Australian Commonwealth Shipping Co. was chiefly eventful on account of Tremellen's development and tests of his theory of the source of atmospherics. We also wish to thank the owners, captain and officers of the S.S. "Boonah" of the Australian Commonwealth Shipping Co. for their invaluable aid.

Very great assistance was given to Mr. Tremellen in Australia by Mr. Fisk and the engineers of the Amalgamated Wireless Co. of Australasia, who have, since the expedition, carried out further extensive tests along similar lines.

The major portion of the theoretical work in this paper is due to Mr. T. L. Eckersley, and the preparation of the paper itself is the work of Mr. Eckersley and Mr. Tremellen.

A considerable amount of data will be published later, particularly that referring to the absolute readability of signals through atmospherics, this having been held back for commercial reasons.

THE MEASURING INSTRUMENT AND ITS CALIBRATION.

In order to give a fairly just idea of the accuracy to be expected in this work of signal measurement, it will not be out of place to give a brief description of the principles and details of the measuring instrument and its calibration. A fairly detailed description of the instrument has already been given before the Institution, and it will therefore be sufficient, for the sake of completeness, to indicate here, in as concise a manner as possible, the general principles, the accuracy of calibration and of the measurements, and the modifications which nearly two years' work with it have rendered possible or advisable.

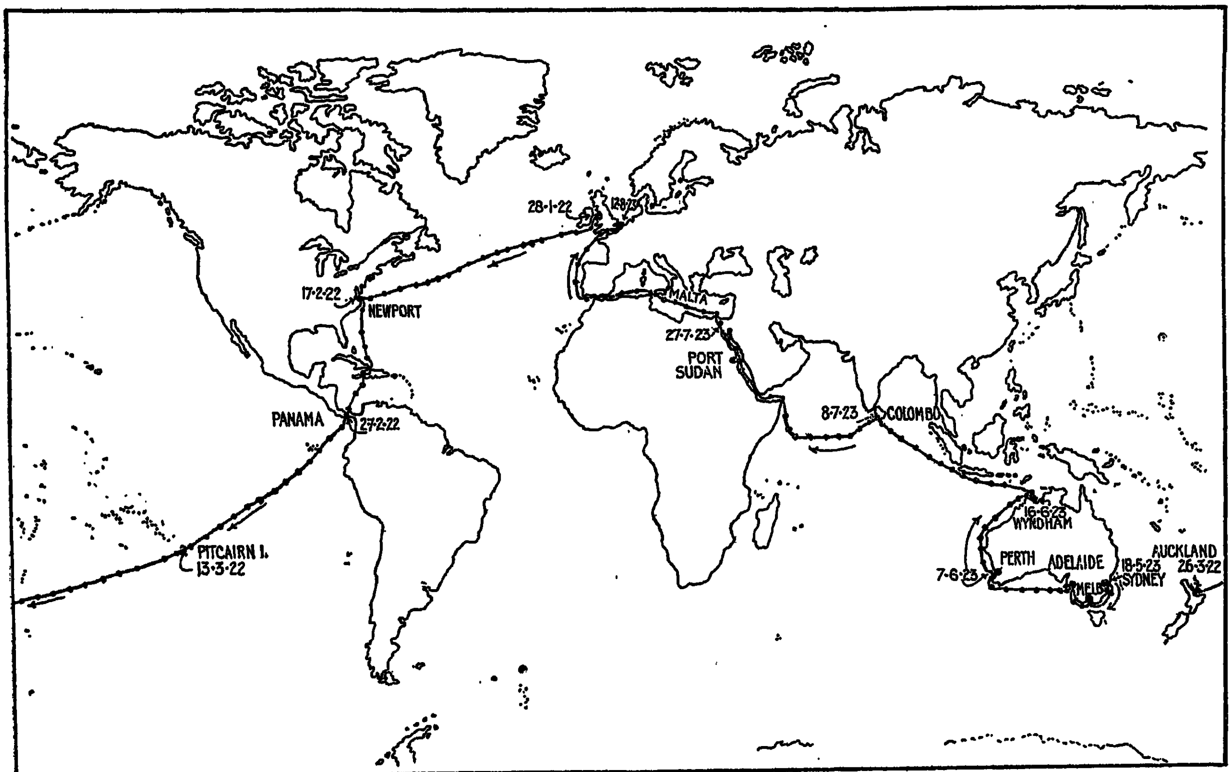
Signal measurement set.—The method consists essentially in providing an artificial continuous-wave signal (of the same frequency as the signal to be measured) the intensity of which can be varied over wide limits and measured with a fair degree of accuracy. This artificial signal can be introduced into the aerial or, alternatively, into a dummy circuit having the same electrical constants as the aerial, coupled to the receiving apparatus.

The strengths of the received signals in the dummy aerial caused by the artificial signal, and of those in the aerial caused by the incoming signal, are compared and equalized by varying the strength of the former. The calculated E.M.F. induced in the dummy or aerial by the former is then the same as that induced in the aerial by the signal.

The instrument therefore primarily measures the actual intensity of E.M.F. induced by the signal in the actual aerial used, but it is not a big step to infer from this the actual strength of the electric field in the incoming wave.

The artificial signals are supplied by an oscillator in a shielded box, coupled to an intermediate circuit in which the current can be accurately measured.

This intermediate circuit is coupled to the common part of the aerial and dummy circuit by means of a calibrated mutual inductance M, which is well shielded in a copper box. The R.M.S. electromotive force induced in the dummy circuit is then pMI, where I is the R.M.S. current in the intermediate circuit, and $p = 2\pi \times$ frequency.



Map showing the daily positions for the outward and homeward voyages.

Very perfect shielding is necessary to prevent any stray unmeasured E.M.F. from the oscillator being induced directly in the receiver. The whole scheme of connections is shown in Fig. 3, and Figs. 1 and 2 show views of the instrument itself.

The receiving apparatus, consisting of tuned circuit, amplifier and separate heterodyne, may be of any form suitable for receiving the particular signals required; all this apparatus should be preferably shielded in a metal box, for this helps to prevent any direct action of the signal on the amplifier.

The heterodyne signals should, if possible, be introduced into the last valve of the amplifier, as this ensures equality of effect on the dummy and aerial circuit signals.

With this apparatus it is possible to measure to about

10 per cent accuracy the actual E.M.F. induced in the receiving aerial by the incoming signals (under all but exceptional conditions of X's). By providing suitable coils, the instrument can be made to cover a wave-length range from about 400 m to 30 000 m.

The experience of the past two years has shown that it is nearly always possible to dispense with the dummy circuit and induce the homodyne signals directly into

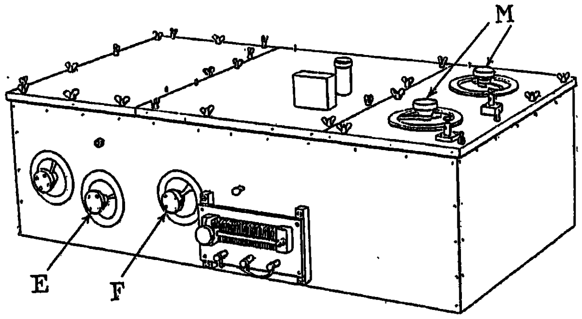


Fig. 1.

the aerial during the intervals when the transmitter is not sending. This procedure is certainly more accurate. In the first place it avoids the error consequent on the dummy circuit being not quite identical with the aerial; and it is difficult sometimes to ensure that the dummy circuit and aerial are even approximately the same. In the second place, when inducing direct into the aerial, the induced signal from the homodyne and

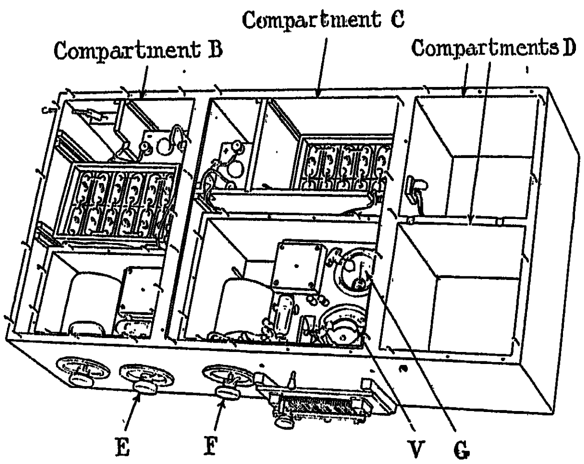

Fig. 2.

the incoming signals are under the same conditions as regards jamming and strays, which is a great advantage in matching the two accurately.

Calibration, capacity, mutual, effective height overall.—The aim or purpose of the instrument is to enable one to induce a *known* small E.M.F. in the common part of the aerial and dummy circuit (see Fig. 3) by means of the mutual inductance M. It is necessary then to know the E.M.F. induced in the secondary, i.e. pMI, where $p = 2\pi \times$ frequency, M is the mutual inductance, and I is the current in the primary of M, i.e. the intermediate circuit of the signal measurement instrument. The frequency is determined by ordinary wave-length methods (and can be compared accurately with any known standard). The current I is determined by measuring the maximum voltage across C, the intermediate circuit condenser, according to the relation $I_{max.} = CpV_{max.}$

$V_{max.}$ is measured by the potentiometer slide-back method already described by one of the authors (Captain Round) in the *Radio Review.*

Since there has been some doubt about the accuracy of the slide-back method of measuring high-frequency

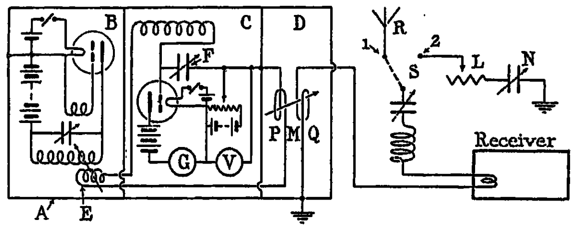

Fig. 3.

voltage,* we may refer here to a discussion of this measurement by Mr. Lunnon on page 304 of Volume 61 of the *Journal.* It would appear from the above that the measurement of pressures above 10 volts is accurate to about 5 per cent, and that by making a constant known correction for each valve the accuracy will probably be quite sufficient for the purposes required. These considerations are further checked by an overall calibration of the measuring instrument, involving of course the signal voltage measurement. This checks within the limits of the experimental errors.

The capacity C is determined by substituting a known, calibrated, variable air condenser. In general it is

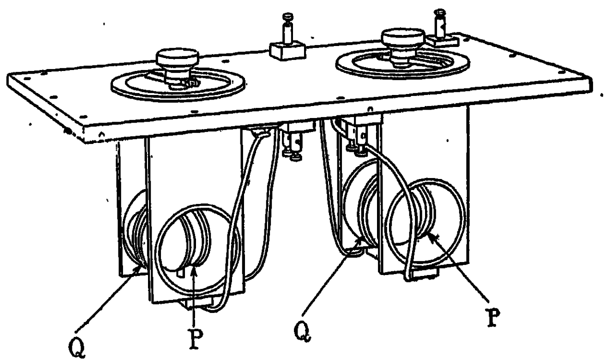

Fig. 4.

arranged that C shall be relatively large in any measurement, so that stray capacities can be neglected.

The mutual inductance M was measured at low frequencies by comparison with a known, standard mutual inductance (Campbell patent type) and checked at higher frequencies by another method. It was possible to neglect the effect of mutual capacity between the primary and secondary, since in all cases the primary of M formed only a very small fraction of the self-inductance of the intermediate circuit. Mutual inductances covering two ranges are shown in Fig. 4.

* E. B. Moullin: *Journal I.E.E.*, 1923, vol. 61, p. 295.

In terms of the known quantities the E.M.F. induced in the aerial could be calculated from the formula:

$$E = \frac{2\,515\, MCV}{\lambda^2}$$

where M is in microhenrys, V is in volts, C is in microfarads, and λ is the wave-length in metres.

This gives the E.M.F. induced in the dummy circuit or aerial, which is made equal to the E.M.F. induced by the signal in the aerial (V say).

In order to infer the amplitude of the field of the wave, the effective height of the aerial must be known. For if E is the voltage per cm in the wave and h is the effective height in cm, then Eh = total voltage induced by the signal in the aerial, i.e. V, or $E = V/h$.

Effective heights.—The quantity we wish to measure is, by definition, the ratio between the actual voltage induced in the aerial, which can be measured directly by means of the signal measurement instrument, and the actual field strength E, in volts per metre say, in the wave-front. Perhaps the most satisfactory way, theoretically, is to measure E actually by means of a frame and compare it with a simultaneous measurement of V, the total voltage induced in the aerial.

There is little doubt that, within the accuracy required, the field strength E can be deduced from voltage measurements made with a frame, when the frame dimensions are known and when suitable precautions are taken. The relation between V and E is then $V = 2\pi AE/\lambda$, where A is the area of the frame and λ is the wave-length.

The other method is to produce a known value of E by means of a second transmitting aerial situated some little distance away, sending with a known current from an aerial of known effective height. Apart from the last difficulty, we are dependent in this case upon an accurate knowledge of the transmission formula for transmission over semi-conducting earth. This knowledge is, as far as the authors are aware, lacking up to the present, so that any experiment depending upon this method must be considered to be inaccurate to an extent proportional to the inaccuracy of the transmission formula used. The correct method is doubtless the former, and would be universally used were it not that it is a particularly difficult measurement to make. The difficulty lies in the fact that it is almost impossible to ensure that the voltage measured is that induced in the frame and that no difference of potential between the frame and earth is included in the measured value of V.

A very symmetrical circuit must be arranged to ensure that this " vertical component " is balanced out. With regard to the second method, which involves the transmission formula, no difficulty is experienced if we assume that the earth is perfectly conducting, for in this case we know definitely from the work of Hertz that the E.M.F. can be calculated with sufficient accuracy from the formula $E = 120\pi h\, I/(\lambda d)$, when d is more than a wave-length.

In this case a method due to Commander Pession, of the Italian Navy, in which three aerials are used, can be successfully employed to determine the experimental effective height of each. Briefly the method may be described as follows:

Let A, B, C be any three radio stations. If A sends to B with a known transmitting current and B measures his received current, aerial resistance, wave-length and distance, then the product $h_A h_B$ can be determined from the transmission formula, for

$$h_A h_B = \frac{\lambda d R i}{120\pi I}$$

where the quantities are all known, namely, I the transmitting current, i the received current, λ the wave-length, R the resistance of the aerial, and d the distance apart of the stations.

Now the ratio of h_A to h_B may be determined at C, for the relative strength of signals at A and B respectively depends on the ratio of the effective heights h_A and h_B, the other quantities entering into the determination being observed or measured. The product and ratio of h_A and h_B both being known, the values of each, i.e. h_A and h_B, may be separately determined.

With regard to the accuracy of the Hertzian transmission formula, we have fortunately in the work of Sommerfield a very complete discussion of the field produced by a radially symmetrical transmitting aerial sending radio waves over the surface of a semi-conducting medium. A result that may be gleaned from this work is that the form of the transmission formula, i.e. $AhI/(\lambda d)$ is correct up to a distance which is large compared with the wave-length if the conductivity is sufficiently great. The determining factor is the quantity which he calls a, namely,

$$a = \frac{x_1^2}{x_2^2}\sqrt{\left(\frac{k_1^2 - k_2^2}{k_1^2}\right)}\sqrt{\left(\frac{rk_1}{2i}\right)}$$

where $k^2 = \dfrac{\epsilon\mu n^2 + i\mu\sigma n}{c^2}$

ϵ = dielectric constant,
μ = permeability,
n = frequency,
$x_1^2 = \dfrac{k_1^2}{\mu_1}$ and $x_2^2 = \dfrac{k_2^2}{\mu_2}$
σ = conductivity,
r = distance,

and the suffixes 1 and 2 refer to the air and earth respectively.

He shows that in order that the transmission from $E = AhI/(\lambda r)$ may hold, the quantity a^2 must be small compared with unity; this quantity is approximately equal to $\pi r/[\lambda(\epsilon_2 + 2\pi i\{\sigma c\lambda\})]$, and is small in all practical cases for values of r equal to many wave-lengths.

Unfortunately, Sommerfield's work is not in such a form that A and h can be determined from the physical dimensions of the transmitter, so that we cannot assume $A_0 = 120\pi$ as in the Hertzian formula. It will be observed that the error in the Pession three-aerial method is an error in scale, so to speak, occasioned by using the value 120π instead of A_0, whatever it.

may be. According to the measurements we have made, however, the difference between A_0 and 120π appears to be too small to be measurable with any accuracy.

The procedure was briefly as follows. The three-aerial method was used to determine the effective heights of aerials at Broomfield, Writtle, and the "College" (Rectory-lane, Springfield) respectively, assuming $A_0 = 120\pi$. A frame aerial was then erected at Broomfield and the E.M.F. due to a signal from the Writtle aerial was determined by means of the signal-measuring apparatus. The observed value of E.M.F. induced in the frame was then compared with the E.M.F. calculated on the basis of the 120π formula, with the value of the effective height of the transmitter, also determined on the assumption that the 120π formula was correct. The agreement was satisfactory and therefore suggests that the 120π formula is sufficiently accurate for all ordinary practical working. With this preliminary we may go on to describe these tests more in detail.

After the first instrument had been designed and calibrated by methods already described, during the early months of 1921 we turned our attention to the determination of the effective height of our receiving aerial, which was erected at Broomfield. Incidentally, this provided a check on the accuracy of the signal measurement instrument. Thus:—Suppose that in measuring the effective heights by the three-aerial method the transmitting aerial A employs such a large transmitting current that the received current in B, say, could be measured by ordinary methods, i.e. thermo-ammeter, or slide-back voltage across a known inductance, then the induced E.M.F. $V = Ri$, and the transmitting current I in the transmitter A, could be measured by methods the accuracy of which is known. If now the transmitting current in A be reduced to such a value I' that the received signal E.M.F. V' can be comfortably measured by the signal measurement instrument, then the ratio of V' to I' should be the same as the ratio of V to I if the instrument is calibrated correctly. The value of V'/I' in terms of V/I will constitute a check on the accuracy of the previous methods of calibration of M, C, etc.

Experiments were carried out during March 1921 with this double aim, and the results will be given briefly here.

The three aerials used formed a triangle one end of which was at Broomfield, another at the College (Rectory-lane, Springfield), and the third at Writtle. The distances were taken from the ordnance map and were well over a wave-length in every case. The received currents were measured in each case by the following methods:

(a) An accurately calibrated thermo-ammeter;

(b) Slide-back voltage across a known inductance; and in all cases a satisfactory agreement was obtained.

The resistance was measured by the slide-back method (the reduction in current on inserting a known resistance being noted) already described. The wave-length used was about 900 m.

The results obtained were as follows:

(1) Effective height of Broomfield aerial 10·5 m.
(2) Effective height of Writtle aerial .. 10·5 m.
(3) Effective height of College aerial .. 14·8 m.

The calculated effective height of Broomfield aerial is 16·1 m (on the assumption that the earth is perfectly conducting); and that of Writtle aerial is 15·3 m.

It will be seen that the observed values are in each case much less than the calculated values. This is no doubt largely due to the capacity of the aerial to the masts and stays; in the Broomfield aerial the central mast and stays are very close to the aerial.

The Broomfield receiving aerial was modified later, first in order to avoid the central supporting mast and its uncertain capacity to the aerial, and secondly to make it simpler, more portable, and easier to erect, so that similar aerials could easily be erected elsewhere. This was to make comparative measurements possible.

This aerial was held up by two 70 ft. steel section masts 200 ft. apart. It consisted of a single 7/19 phosphor-bronze-wire horizontal member 180 ft. long, and a single vertical wire soldered to the centre of the horizontal member, forming a T. Recent measurements (on 4 700 m wave-length) show that the effective height is practically 14 m. This is the aerial on which all the more important measurements have been made.

Radiation check on calibration.—Writtle was chosen as the transmitting station. The receiving aerial was the original five-mast one erected at Broomfield. Signals were sent out by Writtle on a 5 150 m wave-length, the transmitting current varying from 0·2 to 0·6 ampere. The following table shows the actual E.M.F. (in microvolts), the transmitting current I, and gives the actual E.M.F. observed and the calculated values.

TABLE 1.

Transmitting current, amp.	Microvolts calculated	Microvolts measured	Ratio $\frac{\text{observed}}{\text{calculated}}$
0·50	1 660	1 470	0·89
0·40	1 110	1 115	1·005
0·30	832	778	0·936
0·30	832	758	0·910
0·20	554	558	1·006

Further check.—A further check of the same set was made, using a frame receiving aerial in place of the vertical aerial at Broomfield. This aerial consisted of a rectangle, 30 ft. high by 40 ft. long, supported on two wooden masts 40 ft. high, stayed with rope stays. The frame was oriented so that the transmitting station at Writtle was in its plane.

The effective area of such an aerial can be calculated with a fair degree of precision, and when the effective height of the transmitting aerial is known it should be possible to calculate with fair accuracy the E.M.F. induced in the aerial for a given transmitting current, according to the formula

$$E = \frac{377 h_1 2A\pi}{\lambda^2 d}$$

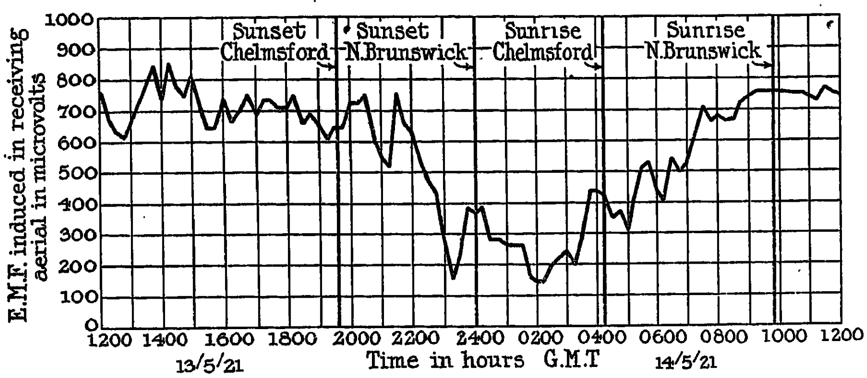

FIG. 5.—Chart showing variation in strength of received signals during 24 hours from 1200 G.M.T., 13 May, to 1200 G.M.T., 14 May, 1921. Transmitting station, New Brunswick; receiving station, Chelmsford.

Effective height of transmitting aerial = 75 m.
Effective height of receiving aerial = 14 m.
Distance = 5 420 km; wave-length = 13 600 m.
Current in transmitting aerial = 550 amperes.
Zenith angle = 48·78°.

Austin-Cohen formula: $I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0 \cdot 0015d/\sqrt{\lambda}}$ gives E.M.F. induced in receiving aerial = 347 microvolts. Mean daylight measured value = 750 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 2 \cdot 16$.

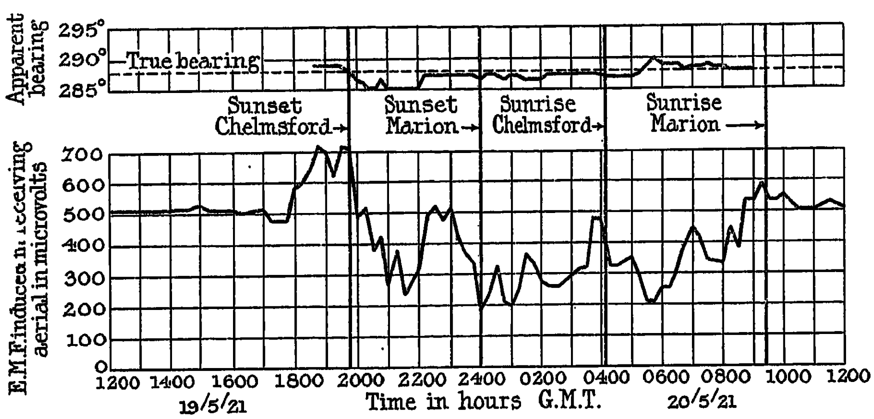

FIG. 6.—Chart showing variation in strength and divergence from true bearing of received signals during 24 hours from 1200 G.M.T., 19 May, to 1200 G.M.T., 20 May, 1921. Transmitting station, Marion; receiving station, Chelmsford.

Effective height of transmitting aerial = 75 m.
Effective height of receiving aerial = 14 m.
Distance = 5 310 km; wave-length = 11 600 m.
Current in transmitting aerial = 380 amperes.
Zenith angle = 47·71°.

Austin-Cohen formula: $I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0 \cdot 0015d/\sqrt{\lambda}}$ gives E.M.F. induced in receiving aerial = 248 microvolts. Mean daylight measured value = 517 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 2 \cdot 08$.

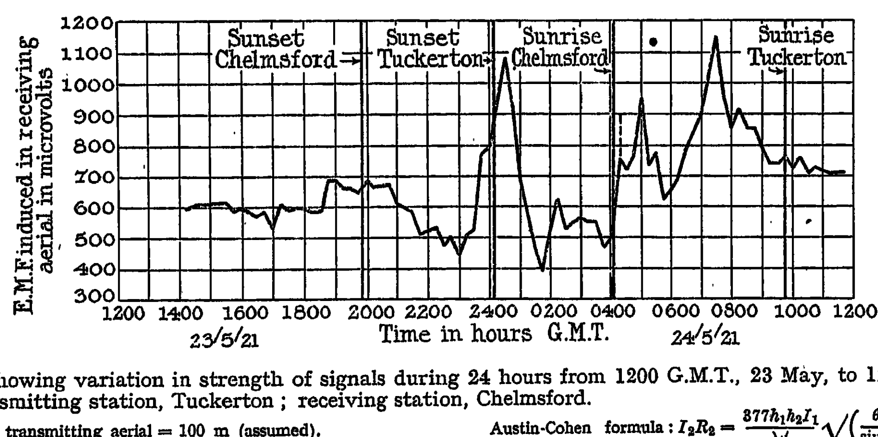

FIG. 7.—Chart showing variation in strength of signals during 24 hours from 1200 G.M.T., 23 May, to 1200 G.M.T., 24 May, 1921. Transmitting station, Tuckerton; receiving station, Chelmsford.

Effective height of transmitting aerial = 100 m (assumed).
Effective height of receiving aerial = 14 m.
Distance = 5 520 km; wave-length = 16 000 m.
Current in transmitting aerial = 400 amperes.
Zenith angle = 48·75°.

Austin-Cohen formula: $I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0 \cdot 0015d/\sqrt{\lambda}}$ gives E.M.F. induced in receiving aerial = 319 microvolts. Mean daylight measured value = 660 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 2 \cdot 07$.

where h = effective height of transmitter,
A = area of frame,
λ = wave-length,
d = distance apart.

This test was made on an 895 m wave-length, transmitting current 2·0 amperes, effective height 10·5 m, d = 2·96 km. The calculated value of the induced E.M.F. was 2 360 microvolts; and the observed value 2 430 ± 130. But the test was extremely difficult and the whole circuit had to be balanced so as to eliminate the vertical component.

These tests show that the accuracy of calibration is sufficient for the purpose.

Original Experiments—American Stations.

The first serious attempts to measure signals with this apparatus were made early in 1921. A more or less systematic set of measurements was made on signals from the Radio Corporation transatlantic stations at Marion, New Brunswick, and Tuckerton, and latterly at Rocky Point. The period during which these measurements were made was from May to practically the end of the year. Measurements were made at Broomfield, near Chelmsford, throughout the whole period, and also comparison experiments were made at various times at Girvan on the west coast of Scotland (near Glasgow), at Towyn in North Wales, and at Poldhu in Cornwall, respectively.

The results of the original experiments made in May 1921 were given in a discussion on long-distance transmission before the Institution,* but will be included here for the sake of completeness.

Figs. 5, 6 and 7 show the result of a 24-hour test carried out as follows:—

May 13 to 14, on New Brunswick;
May 19 to 20, on Marion; and
May 23 to 24, on Tuckerton.

* *Journal I.E.E.*, 1921, vol. 59, p. 677.

Day variations are fairly small but, as usual, night variations are considerable.

The transmission data for the three stations, as well as the mean day received E.M.F. in microvolts per metre, are given in Table 2.

Figs. 8 to 13 show a series of diurnal measurements made simultaneously at Broomfield and Girvan between July 5th and 10th.

Signals are considerably greater at Girvan than at Broomfield, i.e. about 1½ times as strong. This increase is due not only to the reduction in distance (see Table 3, cols. 8 and 9) but also no doubt to land absorption across England and Ireland.

A noticeable feature is that the night variations at Girvan and Broomfield run concurrently and, while the maxima and minima do not occur exactly at the same time, the form of the curve in the two cases is very similar for any given station. There appears to be very little relation, however, between the variations of two different stations; for instance, there is a very marked minimum on New Brunswick at 0300, while the signals in Marion show a peak between 0300 and 0400. Perhaps the difference is partly due to the fact that the curves were taken on different nights, although it is reported from Towyn that the minima at 0300 and 0800 roughly are of regular occurrence on New Brunswick.

A third series of tests was made simultaneously at Broomfield and Towyn (North Wales) during the period August 31 to September 9. Night readings were, however, not taken and attention was confined to day readings, these being very much more constant and reliable. The results are given in Table 4 and show the variations which may occur from day to day.

The signals at Towyn are only slightly better than those at Broomfield, i.e. between 12 per cent and 30 per cent.

A final series of tests was carried out simultaneously at Broomfield and Poldhu (Cornwall). This acts as a check on the Girvan results, for Poldhu is as favourable a site for reception as Girvan, there being no intervening

Table 2.

Date	Station	Microvolts per metre	Wave-length	Transmission current	Height	Distance
1921		μV/m	km	amps.	m	km

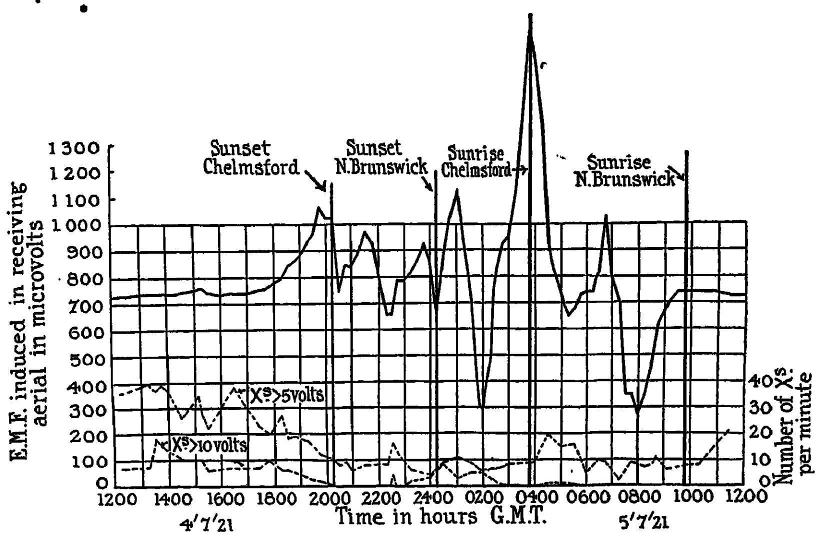
Table 3.

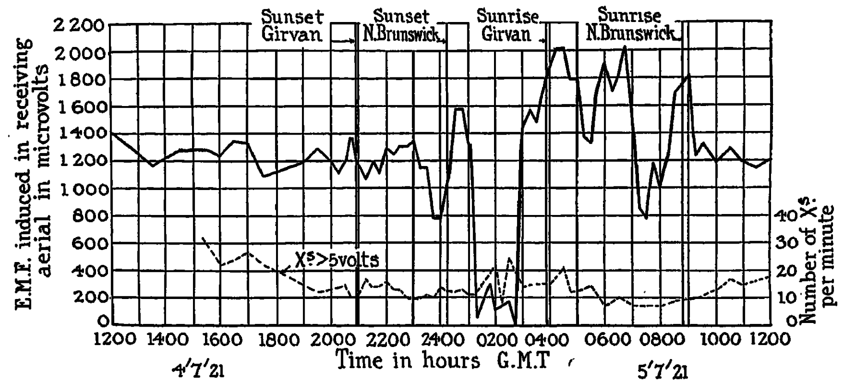
Date	Station	Broomfield	Girvan	Wave-length	Transmission current	Height	Distance from Chelmsford	Distance from Girvan
1921		μV/m	μV/m	km	amps.	m	km	km
May 4–5 ..	New Brunswick	52·8	88·6	13·6	516	67	5 650	5 190
,, 6–7 ..	Marion	40·7	47·8	11·5	530	63	5 310	4 850
,, 8–9 ..	Tuckerton	52·3	90·5	16·0	400	90	5 700	5 250



Effective height of transmitting aerial = 75 m.
Effective height of receiving aerial = 14 m.
Distance = 5 420 km; wave-length = 13 600 m.
Current in transmitting aerial = 516 amperes.
Zenith angle = 48·75°.

Austin Cohen formula:
$$I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0\cdot0015d/\sqrt{\lambda}}$$
gives E.M.F. induced in receiving aerial = 326 microvolts. Mean daylight measured value = 740 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 2\cdot26$.

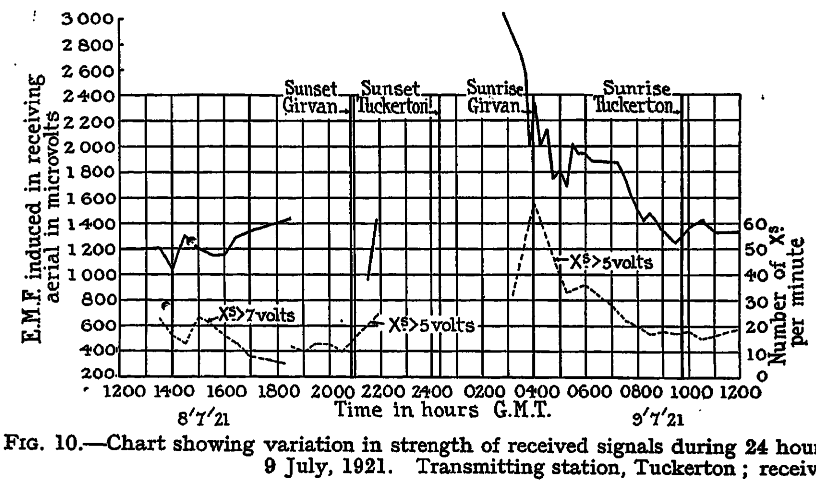
FIG. 8.—Chart showing variation in strength of received signals during 24 hours from 1200 G.M.T., 4 July, to 1200 G.M.T., 5 July, 1921. Transmitting station, New Brunswick; receiving station, Chelmsford.



Effective height of transmitting aerial = 75 m.
Effective height of receiving aerial = 14 m.
Distance = 5 180 km; wave-length = 13 600 m.
Current in transmitting aerial = 516 amperes.
Zenith angle = 46·64°.

FIG. 9.—Chart showing variation in strength of received signals during 24 hours from 1200 G.M.T., 4 July, to 1200 G.M.T., 5 July, 1921. Transmitting station, New Brunswick; receiving station, Girvan.

Austin-Cohen formula: $I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0\cdot0015d/\sqrt{\lambda}}$ gives E.M.F. induced in receiving aerial = 371 microvolts. Mean daylight measured value = 1 240 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 3\cdot35$.



Effective height of transmitting aerial = 100 m.
Effective height of receiving aerial = 14 m.
Distance = 5 255 km; wave-length = 16 000 km.
Current in transmitting aerial = 400 amperes.
Zenith angle = 47·46°.

FIG. 10.—Chart showing variation in strength of received signals during 24 hours from 1200 G.M.T., 8 July, to 1200 G.M.T., 9 July, 1921. Transmitting station, Tuckerton; receiving station, Girvan.

Austin-Cohen formula: $I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0\cdot0015d/\sqrt{\lambda}}$ gives E.M.F. induced in receiving aerial = 370 microvolts. Mean daylight measured value = 264 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 3\cdot43$.

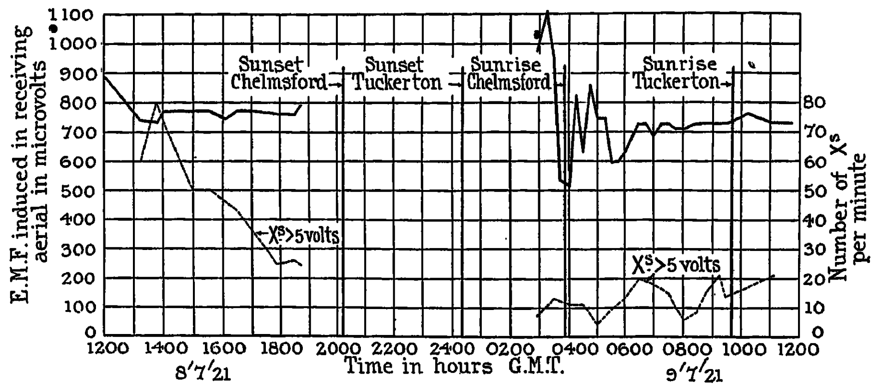


FIG. 11.—Chart showing variation in strength of received signals during 24 hours from 1200 G.M.T., 8 July, to 1200 G.M.T., 9 July, 1921. Transmitting station, Tuckerton; receiving station, Chelmsford.

Effective height of transmitting aerial = 100 m.
Effective height of receiving aerial = 14 m.
Distance = 5 520 km; wave-length = 16 000 m.
Current in transmitting aerial = 400 amperes.
Zenith angle = 49·75°.

Austin-Cohen formula: $I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0\cdot0015d/\sqrt{\lambda}}$ gives E.M.F. induced in receiving aerial = 310 microvolts. Mean daylight measured value = 750 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 2\cdot35.$

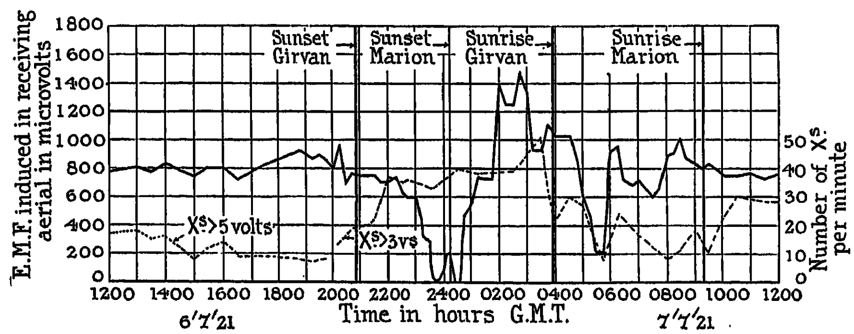

FIG. 12.—Chart showing variation in strength of received signals during 24 hours from 1200 G.M.T., 6 July, to 1200 G.M.T., 7 July, 1921. Transmitting station, Marion; receiving station, Girvan.

Effective height of transmitting aerial = 75 m.
Effective height of receiving aerial = 16 m.
Distance = 4 870 km; wave-length = 11 500 m.
Current in transmitting aerial = 580 amperes.
Zenith angle = 43·87°.

Austin-Cohen formula: $I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0\cdot0015d/\sqrt{\lambda}}$ gives E.M.F. induced in receiving aerial = 455 microvolts. Mean daylight measured value = 806 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 1\cdot77.$

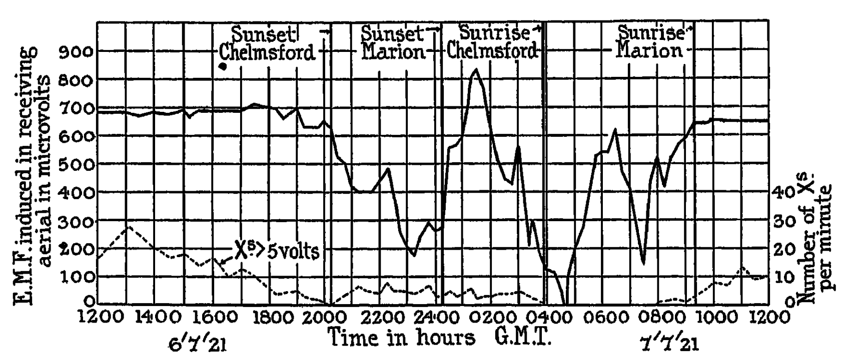

FIG. 13.—Chart showing variation in strength of received signals during 24 hours from 1200 G.M.T., 6 July, to 1200 G.M.T., 7 July, 1921. Transmitting station, Marion; receiving station, Chelmsford.

Effective height of transmitting aerial = 75 m.
Effective height of receiving aerial = 14 m.
Distance = 5 310 km; wave-length = 11 500 m.
Current in transmitting aerial = 580 amperes.
Zenith angle = 47·71°.

Austin-Cohen formula: $I_2R_2 = \frac{377h_1h_2I_1}{\lambda d}\sqrt{\left(\frac{\theta}{\sin\theta}\right)}\epsilon^{-0\cdot0015d/\sqrt{\lambda}}$ gives E.M.F. induced in receiving aerial = 346 microvolts. Mean daylight measured value = 670 microvolts. $\frac{\text{Measured}}{\text{Austin-Cohen}} = 1\cdot94.$

land in either case. These tests were carried out during the period October 11–19, 1921.

The results for the stations WQK (Rocky Point on Long Island) and Glace Bay (GB) (valve set) are included here. WQK had started a service a short while previously, and GB had also been changed from spark to continuous wave and was therefore available for measurements.

The mean daily values of the E.M.F. at Poldhu and Broomfield are given in Table 5.

These results agree roughly with those obtained at Girvan, except in the case of Marion, the signals from which are considerably stronger at Poldhu.

This completes the systematic tests, but a series of sporadic measurements were made at Broomfield during November and December. These show a sudden and

very marked decrease in signal strength on all the American stations during the early weeks of November, and this persisted throughout the winter months. Day-

light variations were also much more marked during the winter than in the summer. The average measurements are included in Fig. 14, which shows the seasonal variation in signal strength from the American stations as measured at Chelmsford. The ordinates, i.e. the signal strength in microvolts per metre, do not represent the actual signal strength received, the values being corrected to bring them all to the same metre-amperes, i.e. 140 000, so that the presentation of the

results is not complicated by individual peculiarities of the stations.

South African Signal Measurements.

Measurements of the signal strength of various stations were also made in South Africa, by Mr. L. D. Hill, with this apparatus during the summer of 1922. The actual period was Aug. 25 to Sept. 12, and therefore represents late summer conditions in Europe and America, and winter or early spring conditions in South Africa.

The results were obtained with measuring and receiving gear almost identical with that used at Broomfield and on the Australian Expedition, the standard aerial of 14 m effective height being used in conjunction with this. This aerial was generally combined with a frame aerial to give a unidirectional or "heart-shaped" diagram, the signals in this case being exactly twice as strong as with the vertical aerial alone when adjusted for maximum reception.

The results are given in Table 6 and Figs. 15 and 16, and show the diurnal variations of WQK and UFT. The latter shows a marked minimum in the half-light half-dark period, which it should be noted only lasts for a brief interval since the stations are on nearly the same longitude. This minimum is not so marked on the American stations and is perhaps due to the fact that the half-light half-dark period was of considerably greater length.

The numerical values of the oversea and overland attentuations derived from this material are discussed in greater detail later, but we anticipate these results so far as to point out that the intensity of signals from European stations, for which the route is all overland,

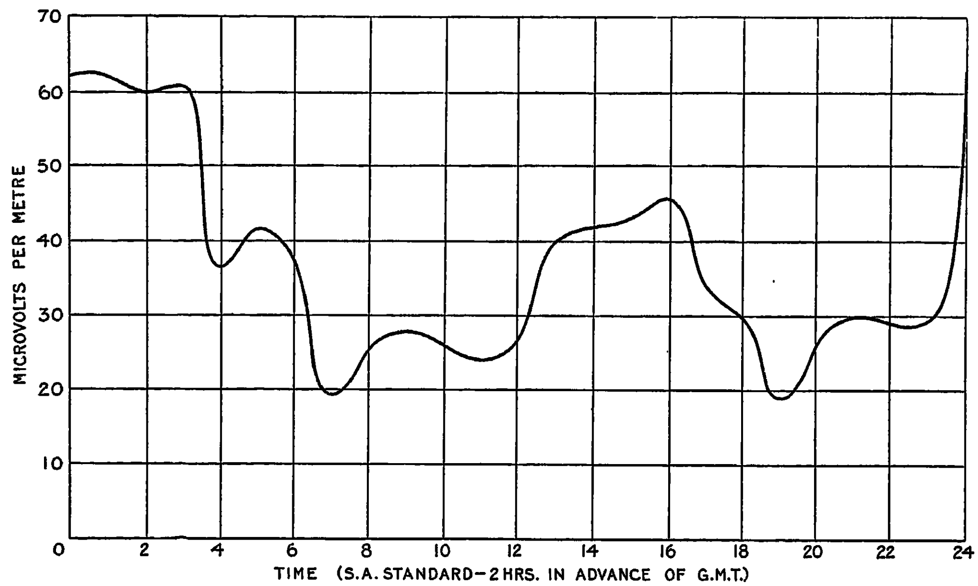

FIG. 15.—Average signal strength of WQK at Kalabas Kraal (South Africa), August–October, 1922.

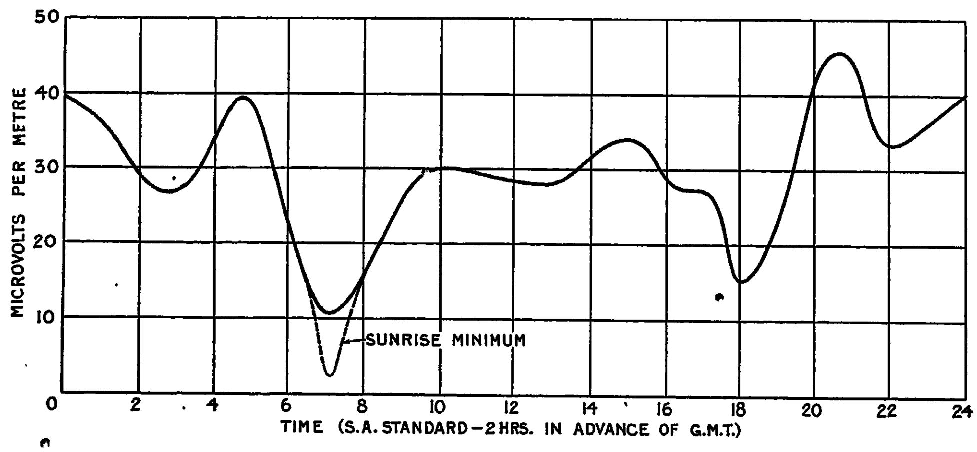

FIG. 16.—Average signal strength of UFT at Kalabas Kraal (South Africa), August–October, 1922.

is approximately halved by the presence of this land, judging by the comparative strength of the American stations for which the path is all oversea.

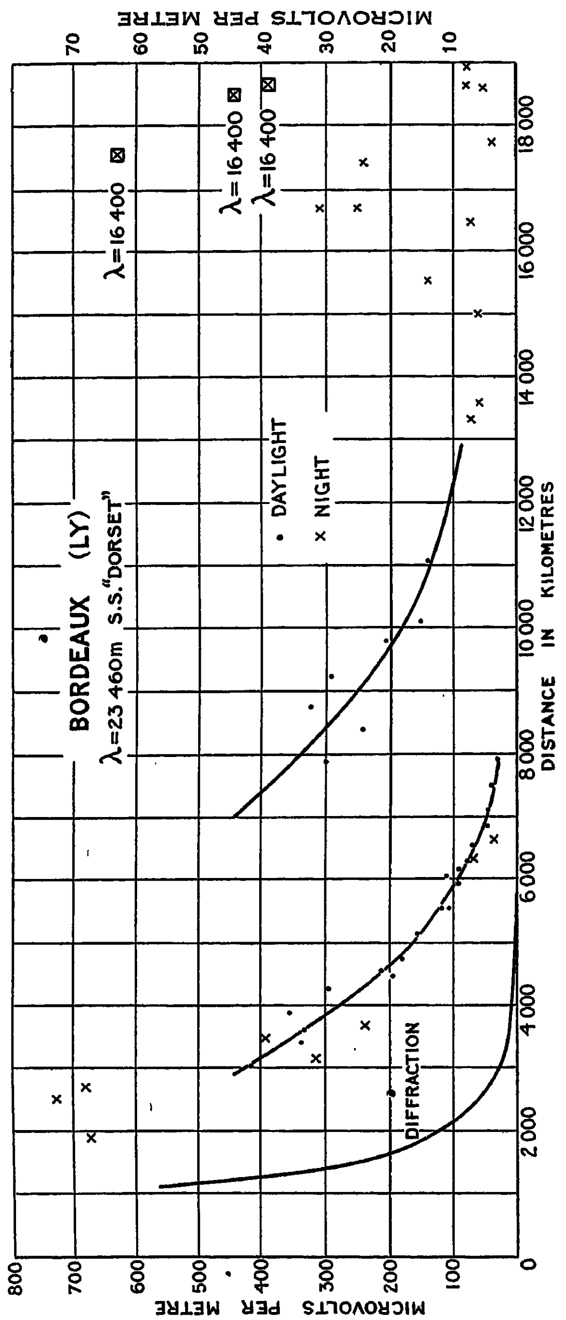

FIG. 17.

LIVERPOOL TO AUCKLAND VIA PANAMA ON S.S. "DORSET."

The following is a discussion of the results obtained on the outward voyage of the S.S. "Dorset" from Liverpool to Auckland via Panama.

Figs. 17 to 30 inclusive show the observed values of microvolts per metre of effective height for various stations, plotted against the distance in kilometres from these stations at the times the readings were taken. The values obtained when both the S.S. "Dorset" and the station under observation were in daylight are shown as dots, and the night readings and readings taken when mixed light and dark conditions intervened are shown as crosses. Although some readings at distances greater than 13 000 km are shown as "all daylight" readings, it is probable that although daylight extended to the North-East from the "Dorset" to the transmitting stations at these times, part or the whole of the signal received was from the South-West, in which direction the great-circle path followed by the signal was chiefly in darkness. The curves are therefore shown dotted at distances greater than 13 000 km. The first indication of any such reversal of signals was noticed on the 18th March, 1922, when in the Pacific Ocean at a distance of about 12 000 km from New York. The signals from the New York stations at certain times of the day, and especially when daylight extended between the S.S. "Dorset" and New York to the North-East, became blurred and often quite unreadable for several hours on the vertical aerial or a plain frame aerial, whereas they were quite readable on the heart-shape or uni-directional receiver. On the latter it was found that the signals at these times were actually received from both directions simultaneously, i.e. from the North-East and also by the long great-circle route of about 28 000 km from the South-West. The signals at these times on the vertical aerial had a sound similar to that given by two continuous-wave signals of slightly varying frequency interfering with one another. Observations taken at these times on some of the curves have been marked as variable due to "beats." This reversal of signals was also noticed on the signals from the European stations, and a similar effect was noticed at about the same time in Rio de Janeiro by the party carrying out experiments at that place. In this case Cavite in the Philippine Islands was the station on which the effect was observed. Where the S.S. "Dorset" approached and then receded from a given station, the observations are distinguished by a circle round the points on the curve. In some cases the diffraction curves have been added for comparison with the observed readings.

In Fig. 27 the majority of the stations measured are shown on the same scale, and relative signals may be seen at a glance.

In Fig. 28, for Honolulu, the arrows through the points denote the direction from which signals were received at the times the observations were taken, taking the top of the chart as North, and it will be seen that the signals received from the West are of greater values than signals at similar distances received from the North. This East and West effect is described more fully in another part of the paper.

Melbourne.—After noting the reversal of signals, as described above, on the S.S. "Dorset" in the Pacific, it was expected that the same would take place at Melbourne, and this was found to be the case. Except in the case of Bordeaux all the European stations reached two maxima or peak values as shown in the curves, one between sunrise at the European station and sunset at Melbourne when signals were from the South-East,

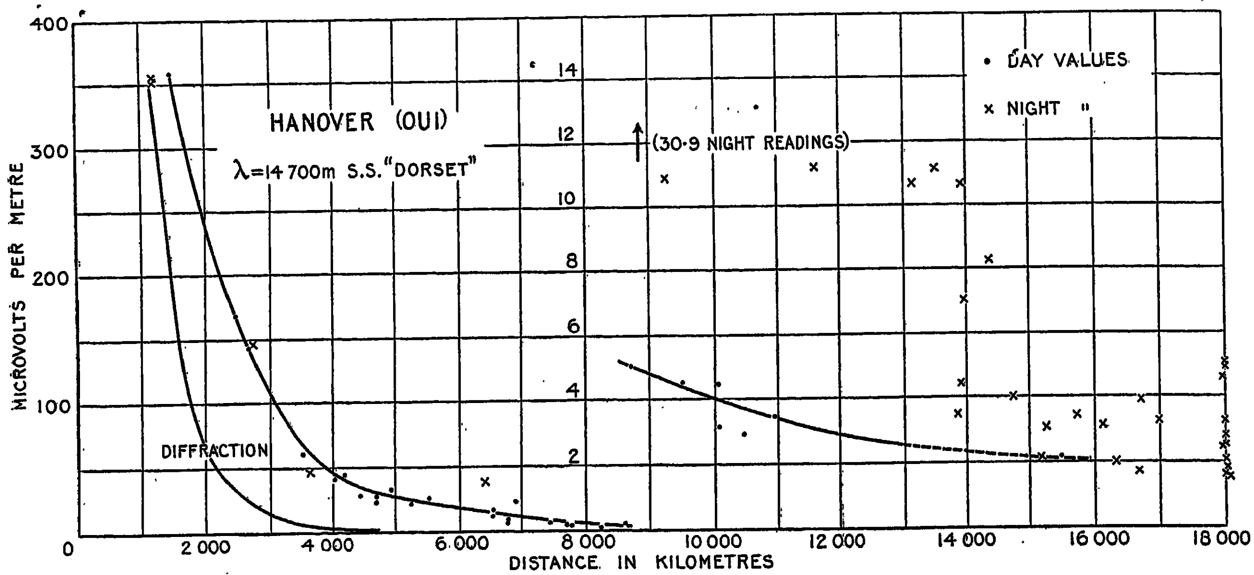

FIG. 18.

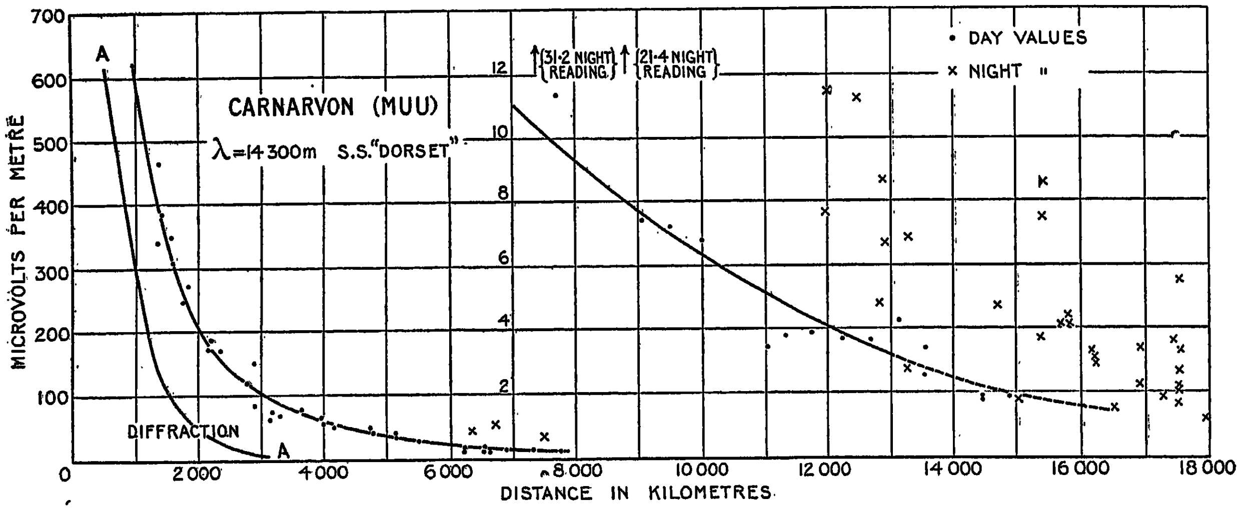

FIG. 19.

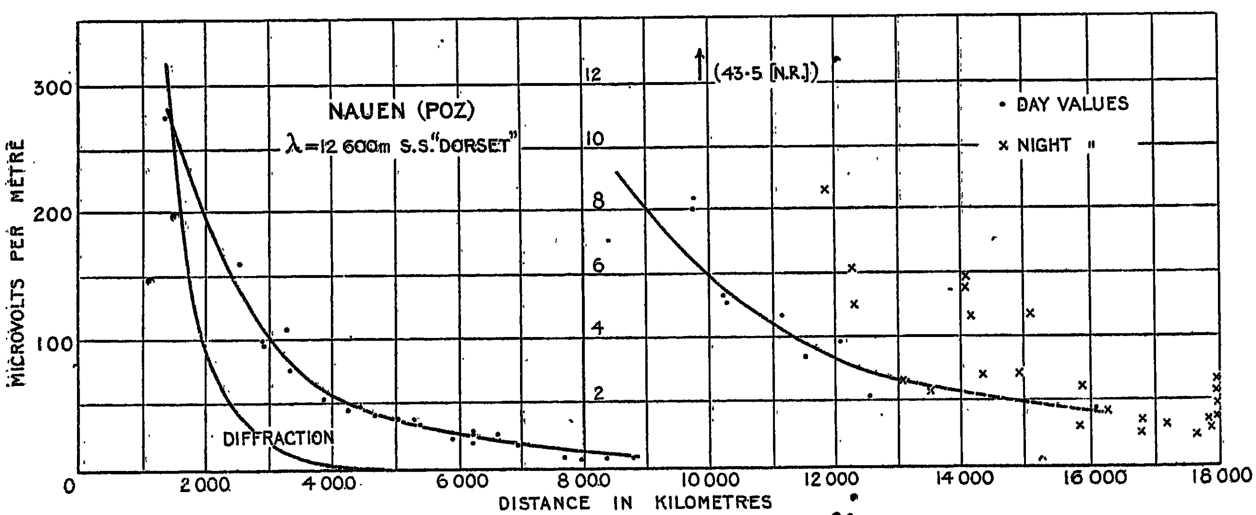

FIG. 20.

NOTE: N.R. = Night reading.

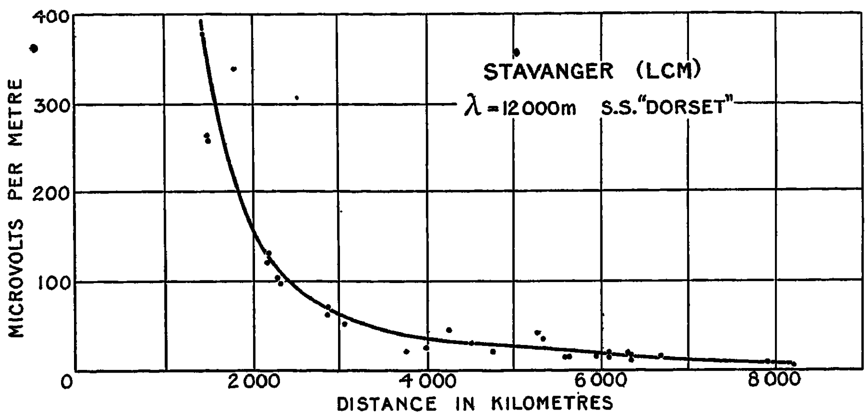

FIG. 21.

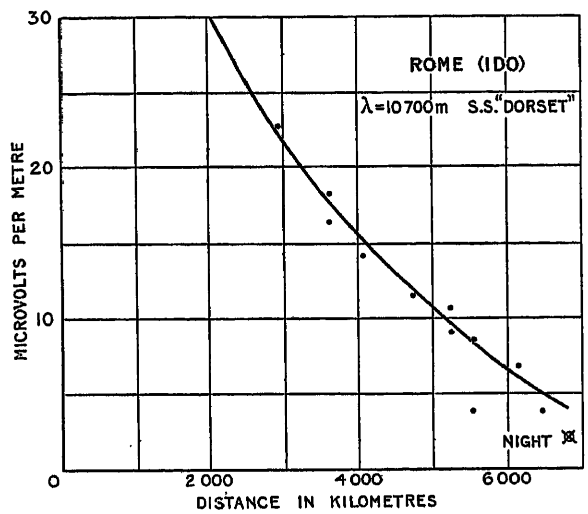

FIG. 22.

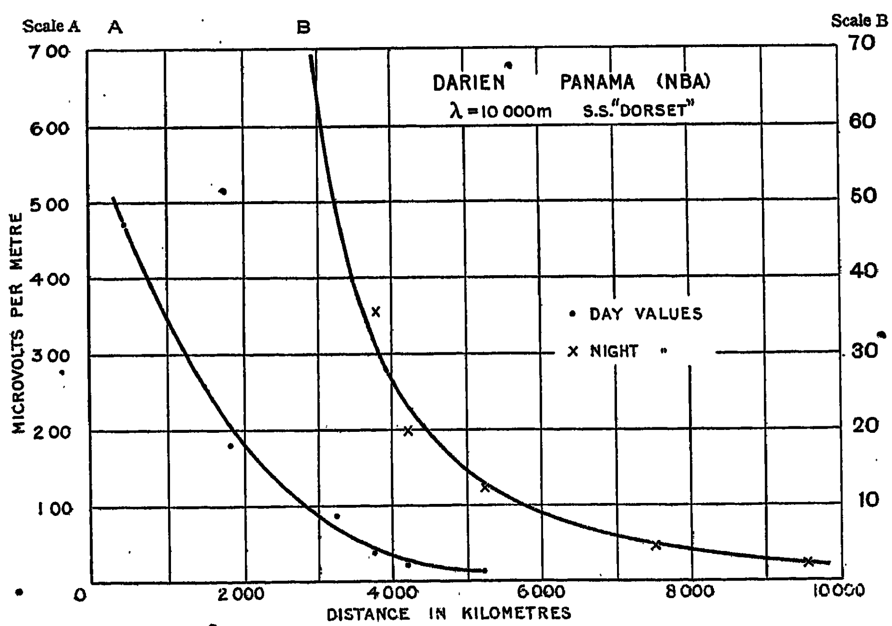

FIG. 22A.

via the Pacific, which route was mostly in darkness at that time, and the other peak between sunset at the European station and sunrise at Melbourne, when the shorter great-circle route via the Indian Ocean to the hood of Melbourne. The majority of these curves give the average of observations extending over a period of four months from the autumn to the spring in Australia, and as the times at which the "peaks" occur

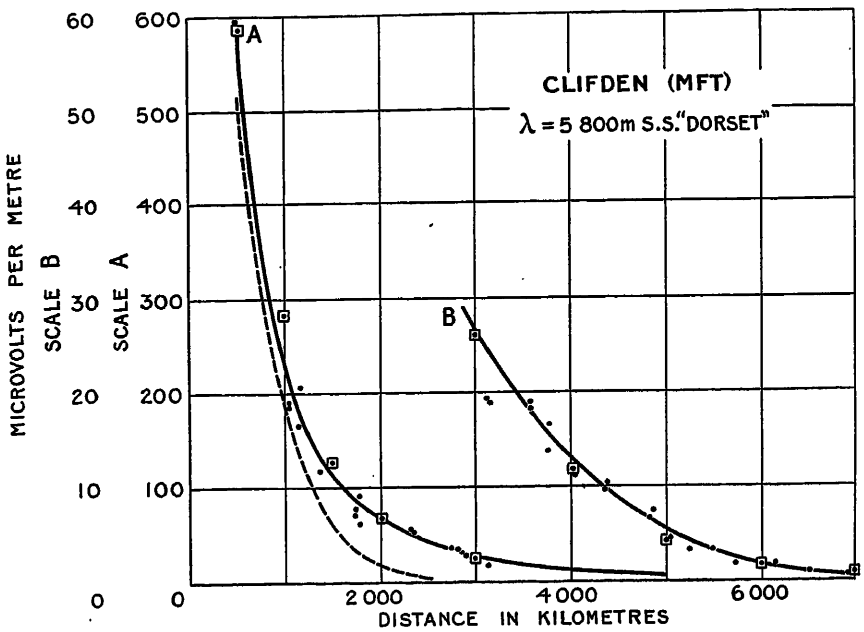

FIG. 23.

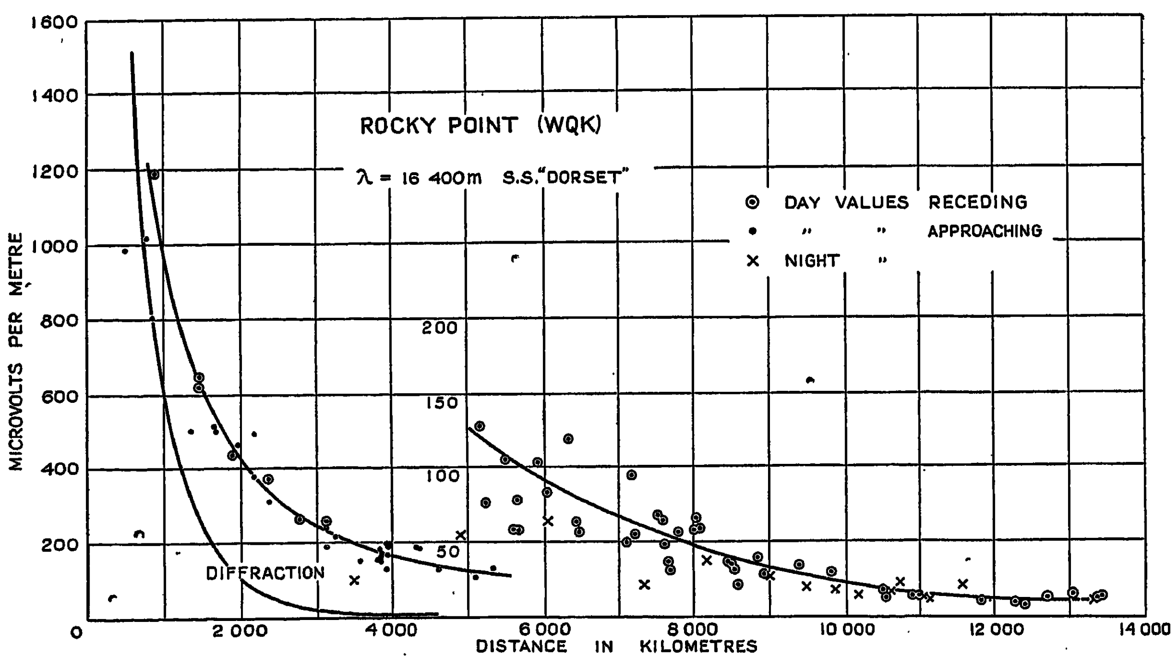

FIG. 24.

North-West was in darkness. The same reversal took place on the signals from New York.

Figs. 31 to 49 inclusive show the average curves for diurnal variation of signal strength in microvolts per metre for various stations observed in the neighbour- vary with the seasons, the peak values appear more variable and extend over rather a longer period than they would if taken over a period of only a few days, although considerable variations in the peak strengths do occur from day to day. The manner in which the

peaks vary with the seasons is shown in Figs. 38 and 44, whilst Fig. 37 shows the variation in the signal strength of Carnarvon for one day.

between 0400 and 0700 G.M.T. appeared to be rather lower than the winter values.

In Fig. 31 it will be seen that signals from Bordeaux

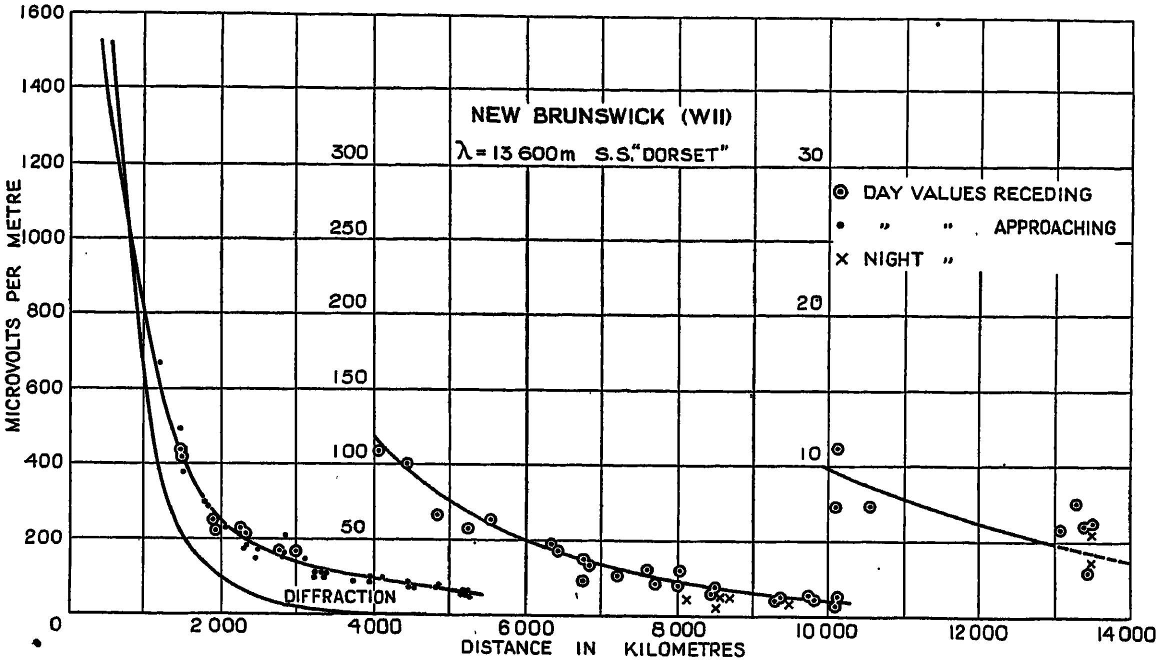

FIG. 25.

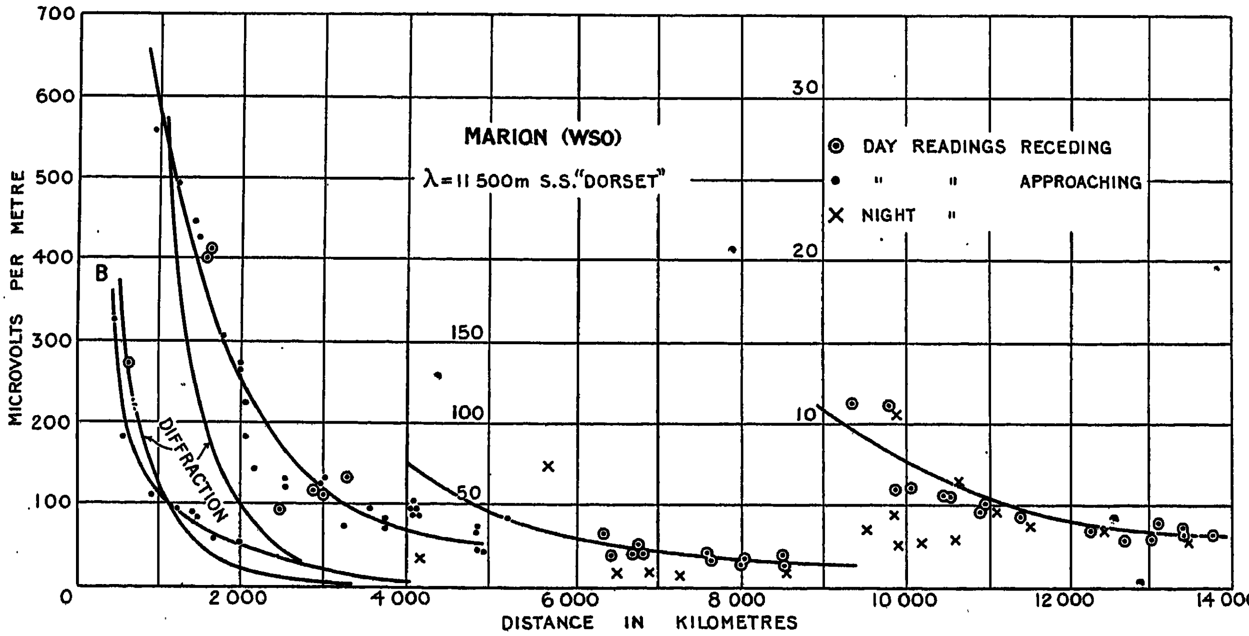

FIG. 26.

NOTE: For "B" curves, multiply the scale reading by 10.

Figs. 32 and 43 give examples of summer conditions and it will be seen that the signal strengths are very similar to the average winter values, though on some occasions the peak values of some European stations

on 23 400 m have no maximum between 0400 and 0800 G.M.T. as in the case of the other European stations, and signals on the unidirectional receiver were at this time always stronger from the North-West, whereas

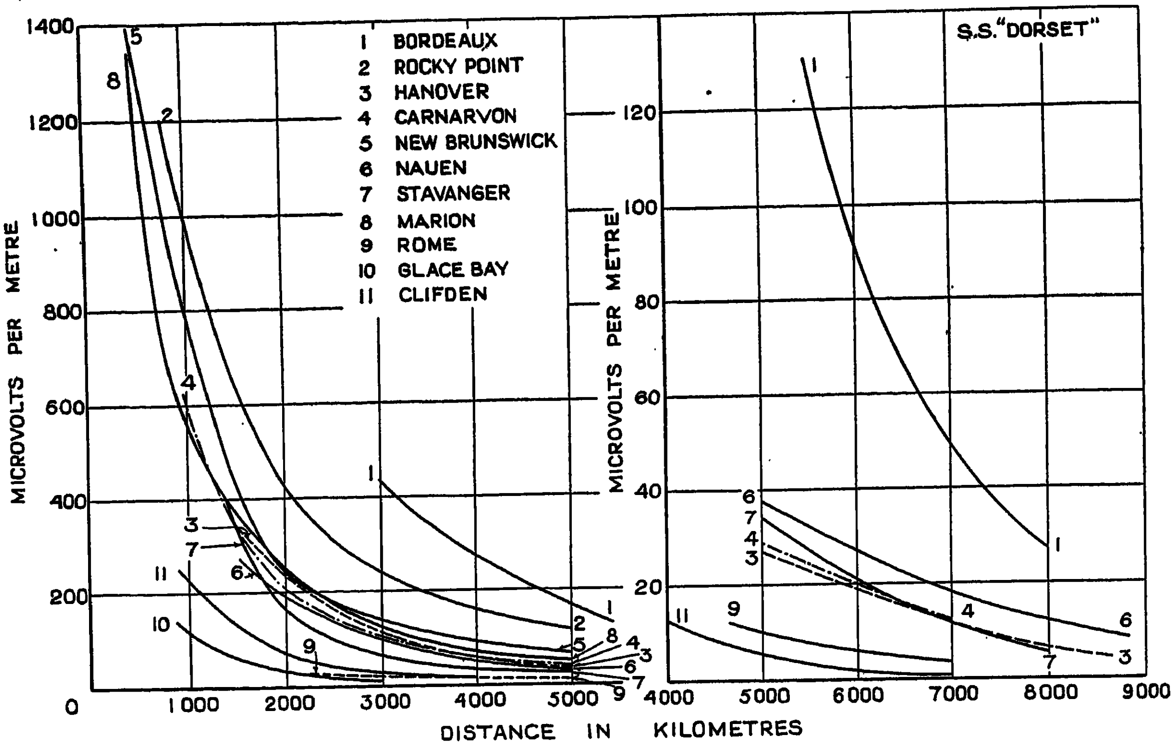

FIG. 27.

signals from the other European stations were always either equal at these times or stronger from the South-

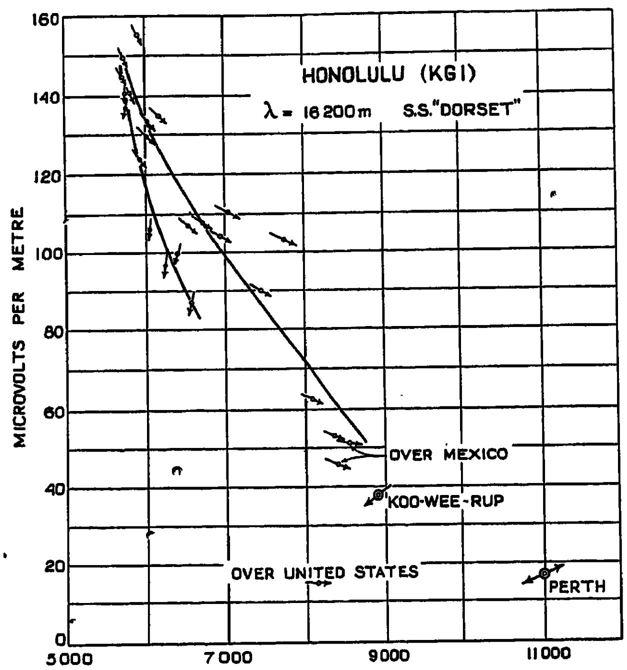

FIG. 28.

East, and, in the case of Carnarvon, Nauen and Hanover, were entirely from the South-East for three or four hours. That this difference in behaviour of signals from Bordeaux is due to the long wave-length of this station compared with the other European stations appears to be borne out by the following observations on the New York stations. Figs. 40, 42, 45, 46 and 47 show that while Coram Hill (WQL) having the longest wave-length of the New York stations reaches very much higher values of signal strength from the South-West than from the North-East, and Rocky Point and Tuckerton are also stronger or about equal in the case of the latter, the New York stations of shorter wave-length, New Brunswick and Marion, are always strongest from the North-East. The times at which the signals from New York change over also vary with the wave-length, the stations of longer wave-length always remaining from the South-Westerly direction after the shorter-wave stations have changed to the North-East, and changing back again to the South-Westerly route before the shorter waves. Owing to the above, in Melbourne at certain times two stations, both in New York, are received one from the North-East and the other from the South-West. At these change-over times New Brunswick was always more variable and appeared to hesitate about changing from one direction to the other for a longer period than the other stations, and this often had the effect of making the signals more readable than the other New York stations at these times, owing to the gain which a bi-directional signal had over a unidirectional signal when the unidirectional signal was from a similar direction to that of the atmospherics at the time.

At times when the signals from the New York and European stations were bi-directional, the beats as

escribed above were observed, and these were especially marked in the case of UFT (Paris), signals from his station being often quite unreadable, due to this ffect, for several hours a day on a vertical aerial or daylight signals, and were very variable in strength. The maximum signals received were always at sunrise at Honolulu. Signals from this station were always from the North-East only, as were signals from KET (San

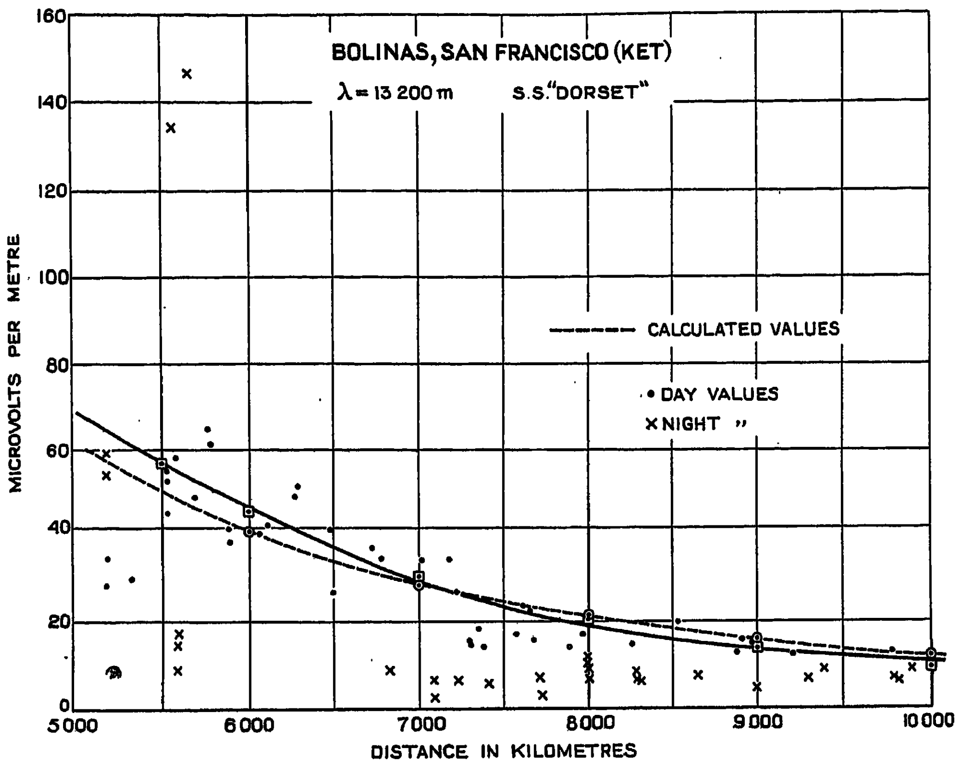

FIG. 29.

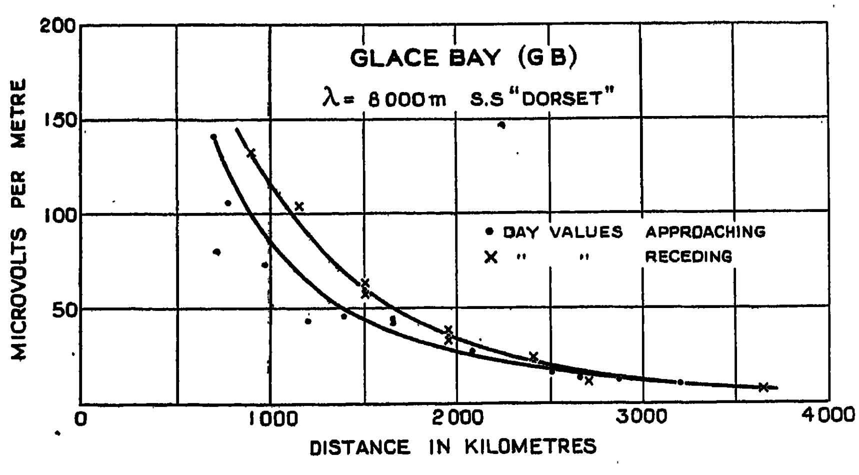

FIG. 30.

frame aerial, but always readable on the heart-shape or unidirectional receiver. These beats were also observed on signals from Honolulu at Perth (Western Australia) and various places in the Indian Ocean on the homeward voyage.

As shown in Fig. 48, signals from Honolulu during the all-dark period never reached the average of the all-Francisco) (see Fig. 49), the curves for these two stations being very similar in form.

Rocky Point and Honolulu being in much the same direction to the North-East of Melbourne, and the wave-lengths of these stations being very similar, it was not always easy to distinguish one station from the other between about 0800 and 1200 G.M.T. when both signals

were received from the North-East, but from about 2000 to 0200 G.M.T., owing to the reversal of the signals from Rocky Point and to the fact that the signals from Honolulu did not reverse, Rocky Point was received on one side of the heart-shape receiver with no trace of Honolulu, while Honolulu was received on the other side with no trace of Rocky Point.

taken at Perth (Western Australia) over a period of about five weeks during the summer. The aerials used at Melbourne and Perth were identical. Comparing these curves with those taken at Melbourne, it will be seen that Bordeaux (Fig. 50) was only heard from the North-West, and in the case of the other European stations (Figs. 51 to 54) signals were always stronger from the North-West,

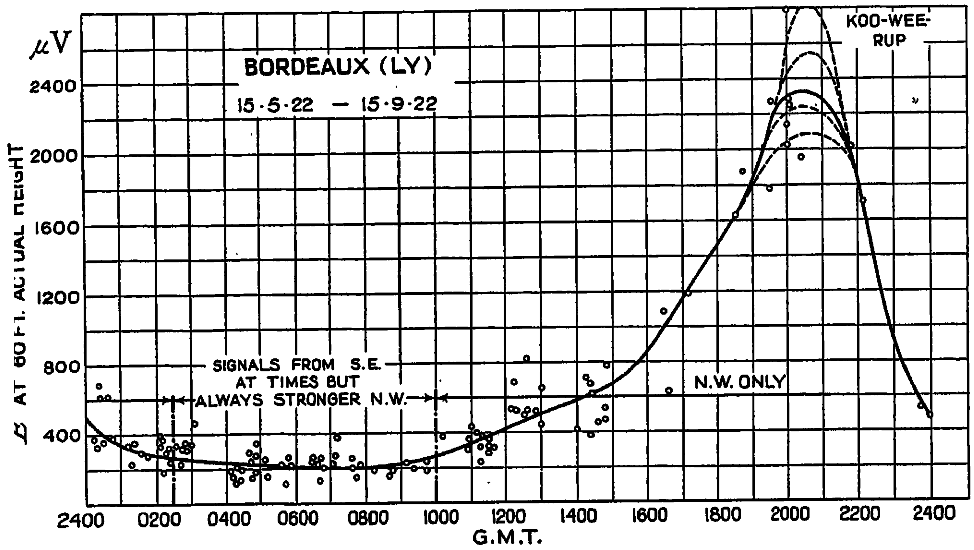

Fig. 31.

Note: Effective height = 12 metres.

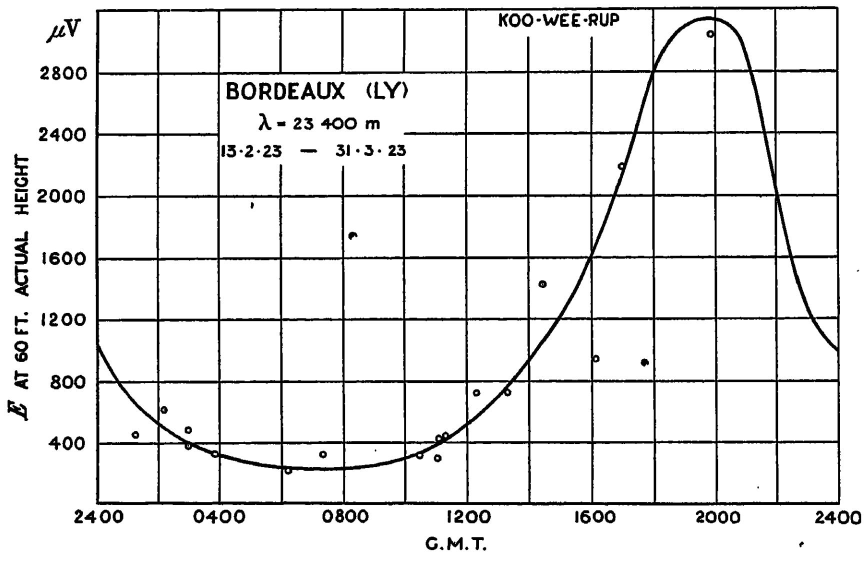

Fig. 32.

Note: Effective height = 12 metres.

Fig. 41 gives an idea of the relative signal strengths of WQL (Coram Hill) on either side of the heart-shape receiver, i.e. from the North-East and from the South-West at and near one of the two change-over periods. The strengths of signals on the vertical aerial are given at the same time as those obtained on the heart shape.

Perth.—Figs. 50 to 59 inclusive show average curves but were audible from about 0600 to 1000 G.M.T. from the South-East also. At these times "beats" were sometimes observed. It should be explained that a bi-directional signal is not always accompanied by "beats"; and the extent to which these "beats" occur, and the consequent mutilation of the signals, varies from minute to minute. Also the worst

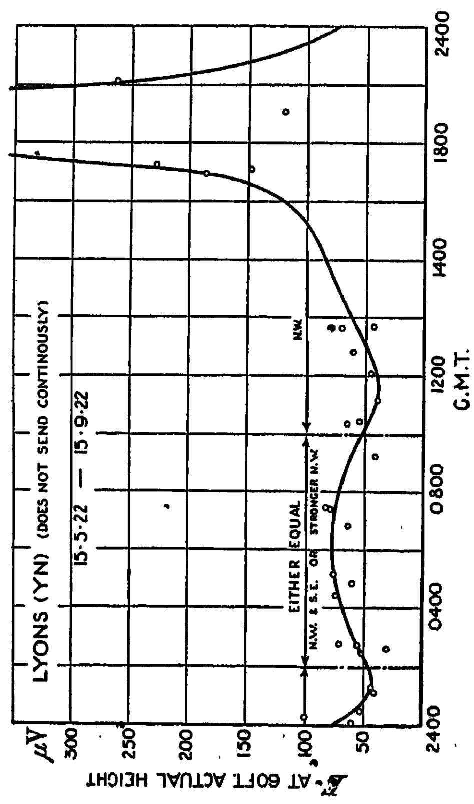

FIG. 33.—At Koo-Wee-Rup.
NOTE: Effective height = 12 metres.

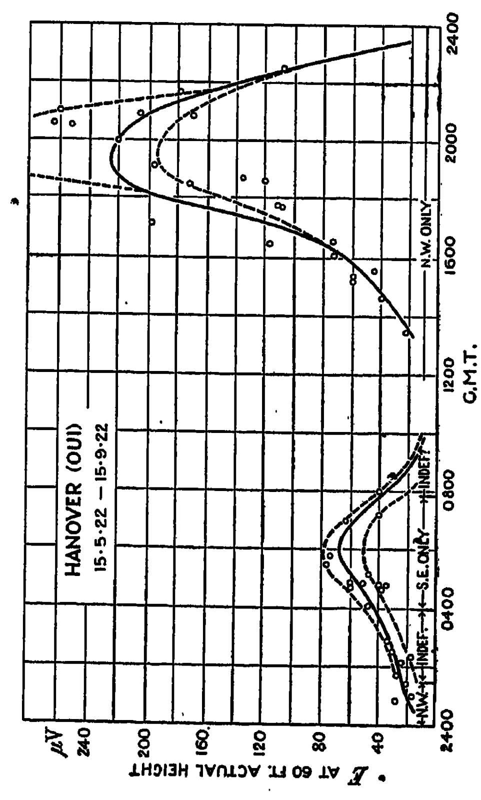

FIG. 34.—At Koo-Wee-Rup.
NOTE: Effective height = 12 metres.

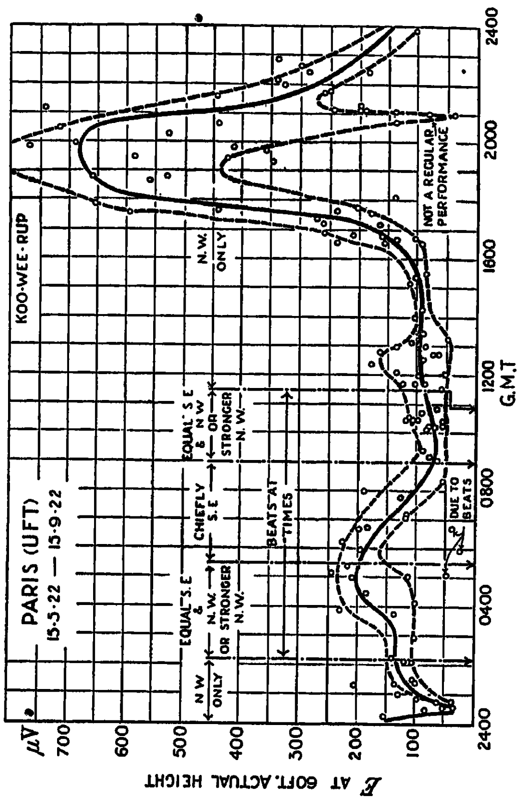

FIG. 35.
NOTE: Effective height = 12 metres.

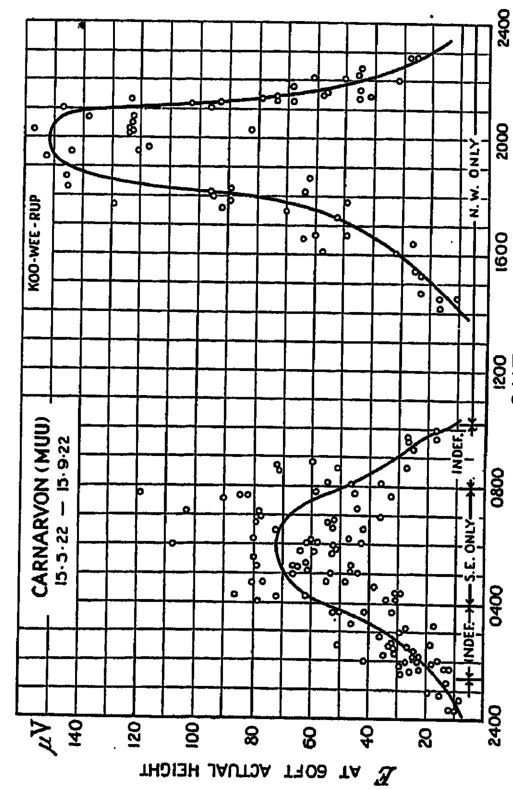

FIG. 36.
NOTE: Effective height = 12 metres.

"beats" do not necessarily occur when the signals received from the two opposite directions are equal in strength; and bad mutilation was often caused when the signals from one direction were quite weak compared that on Tuckerton is greatly reduced in comparison with the peak from the South-West, although Perth is not much more than 1 000 km from the antipodes of New York. Taking the shorter-wave stations, New Bruns-

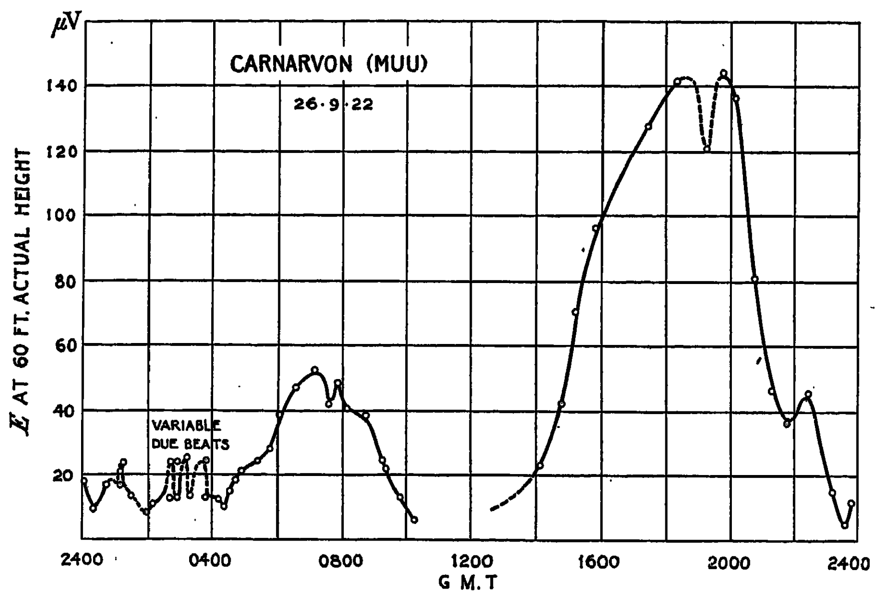

Fig. 37.—At Koo-Wee-Rup.
Note: Effective height = 12 metres.

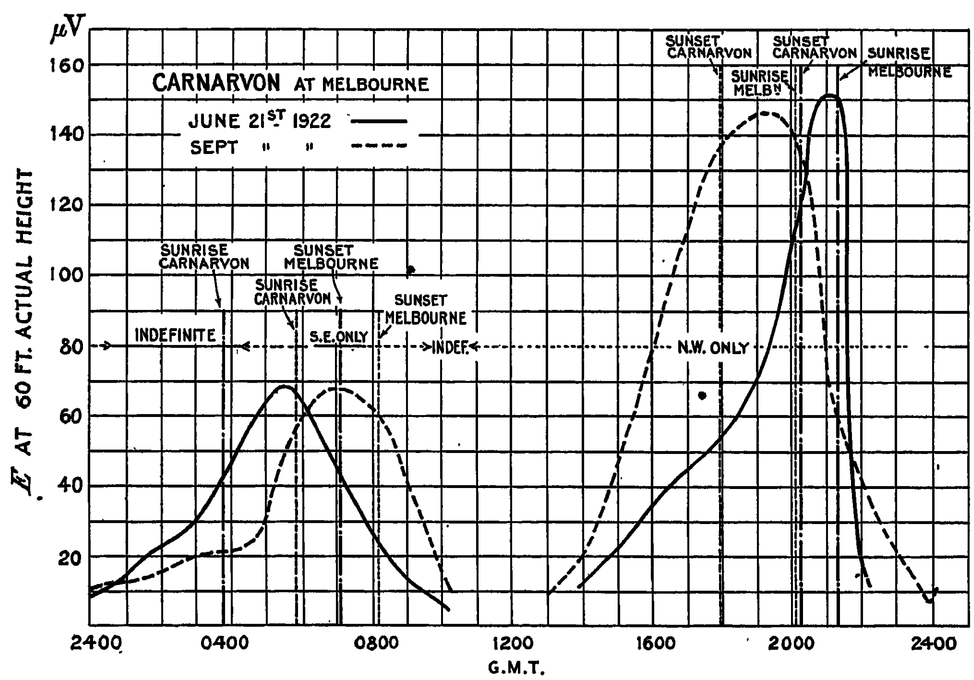

Fig. 38.—At Koo-Wee-Rup.
Note: Effective height = 12 metres.

with those from the opposite direction. Comparing the New York stations at Perth and at Melbourne, it will be seen that the peak on Rocky Point and Coram Hill from the North-East is almost non-existent, whilst wick and Marion, the peak on the former station from the South-West is actually lower than the peak at this time in Melbourne, and the latter station was never heard entirely from the South-West. In this connection

it should be noted that owing to the proximity of Perth to the antipodes of New York there was a difference of 20° or more between stations which, although generally spoken of under a general heading of New York stations, are actually some distance from New York. The bearing of Marion, for example, being only 30° East of North at Perth may introduce an effect which is in some manner connected with the East and West effect described elsewhere. Signals from Marion were not audible over a long enough period to enable sufficient data to be obtained for a curve. This also applies to KET (San Francisco). The latter station was heard on one occasion from the South-West, although for two or three hours during the all-dark period signals from the North-East were usually comparable with those heard at Melbourne. In general, although the all-daylight signals from the European stations were fairly constant, peak values of the all-dark signals were very variable.

Honolulu (Fig. 59) was heard from the South-West at certain times of the day, the signals from this direction being of equal strength to those from the North-East for about two hours of the day, but never stronger than those North-Easterly. The average all-dark signals from the North-East on this station were stronger at Perth than the average all-daylight signals, and although the all-daylight signals were considerably weaker than those at Melbourne, the all-dark signals were actually on an average as strong as, or stronger than, those at Melbourne, and, as at the latter place, signals reached a peak at sunrise at Honolulu.

Melbourne to London on S.S. "Boonah."

Figs. 60 to 79 inclusive give the attenuation curves for various stations obtained on the homeward voyage on the S.S. "Boonah," by way of Adelaide, Perth, Wyndham, Colombo and Suez. The figure at the beginning of this paper (see p. 934) shows the daily positions for the

outward and homeward voyages on the S.S. "Dorset" and S.S. "Boonah."

Fig. 67 for Leafield on 12 300 m shows a marked increase in signal strength near Colombo with the decrease

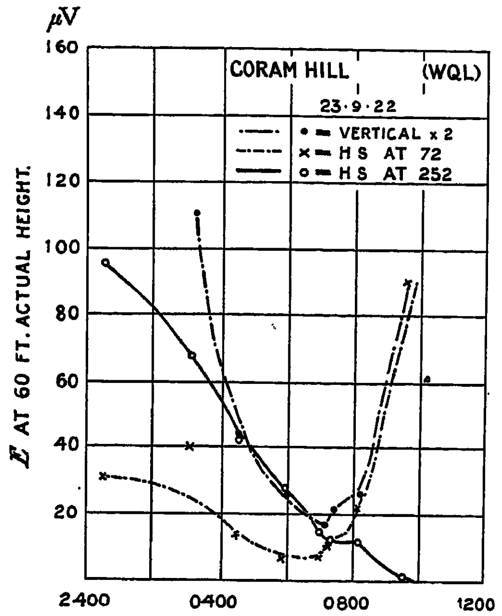

Fig. 41.—At Koo-Wee-Rup.

Note: Effective height = 12 metres.

in the amount of land traversed by the signals in India. This increase was noticed in this neighbourhood on other European stations.

Bordeaux (Fig. 61) was only using a wave-length of 18 000 m, so that no comparison could be made with signals from this station obtained on the outward voyage, during which the wave-length was 23 460 m. The beat effect was very marked on signals from Carnarvon (Fig. 65) whilst crossing the Australian Bight, and there was a period of several days along the North-West coast of Australia during which no signals were heard from this station.

The New York stations (Figs. 71 to 74 inclusive) were heard between Perth and Wyndham only from the South-South-West, and there was a period of several days between Wyndham and Colombo during which no signals were heard from the New York stations, this period corresponding to the time at which the great circle between the S.S. "Boonah" and New York was over or near the North and South Poles. The loss of signals over this period was probably due to the fact that under these conditions the signals have nearly always to traverse a path over which there is a mixture of light and darkness. The arrows show the direction from which the signals were received at the times observations were taken, assuming the top of the page to be North. The wave-length of Coram Hill (Fig. 71) was changed from 19 000 to 17 600 m shortly before leaving Australia.

Unfortunately, Rocky Point worked very little when all-daylight conditions intervened between the S.S. "Boonah" and this station, and it was not possible to obtain a curve from the few readings taken.

Honolulu (Fig. 75), as stated previously, was only received from the North-East at Melbourne, but was bi-directional for some hours a day at Perth. At Wyndham there were only occasional traces of signals from the South-West. Between Wyndham and Colombo signals were bi-directional for several hours a day with "beats," but after leaving Colombo signals were only from the West and later from the South-South-West. When this station was last heard in the Red Sea, signals were received from about North, the great-circle bearing being very near the Polar Circle, and although the distance was actually becoming daily less by this route, no further signals were heard.

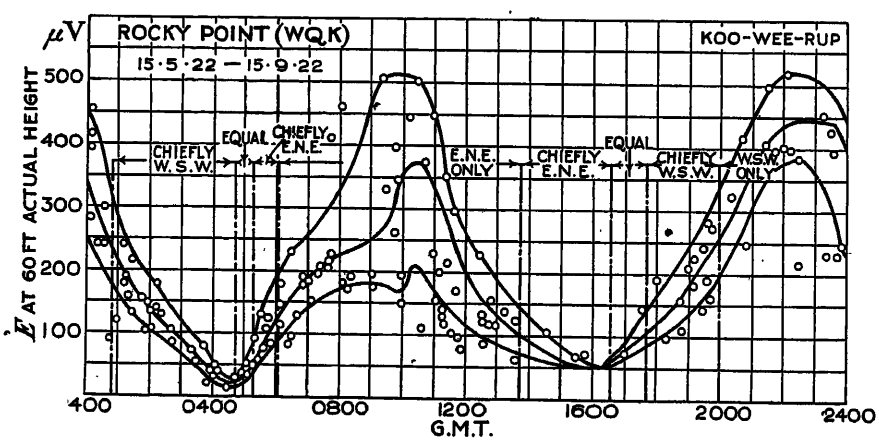

Fig. 42.

Note: Effective height = 12 metres.

Signals from Cavite (Fig. 76) were lost between Colombo and Aden, the attenuation being greater than for the West to East signals received from this station on the S.S. "Dorset." A portion of the attenuation curve obtained in the Pacific is given on this curve for comparison.

General Observations.

Observations were also made both on the outward and homeward voyages and also in Australia, of the signal strength in microvolts per metre which would be required on various wave-lengths at any time and under the varying atmospheric conditions from day to day to ensure perfect readability.

The observed readability of various stations at these times was also estimated both on the vertical aerial and on the heart-shape receiver, so that the gain of the latter over the vertical aerial could be obtained at any time, this gain, of course, being dependent on the relative directions of signals and atmospherics. These results are not included in this paper.

Bearings of Signals.

Bearings obtained on the Bellini-Tosi direction finder in Australia on the long-distance stations, both in Europe and in America, were found to be remarkably accurate and constant. It was only on very rare occasions that any variation of bearing was observed due to the well-known night effect. Even during the change-over periods at times when signals were bi-directional, the bearing remained accurate and unchanged. The nearer stations such as Cavite suffered very much more from this night effect, and it was of fairly frequent occurrence on signals from Honolulu. This effect, which had been noted before this voyage was undertaken, frequently but not invariably occurred simultaneously

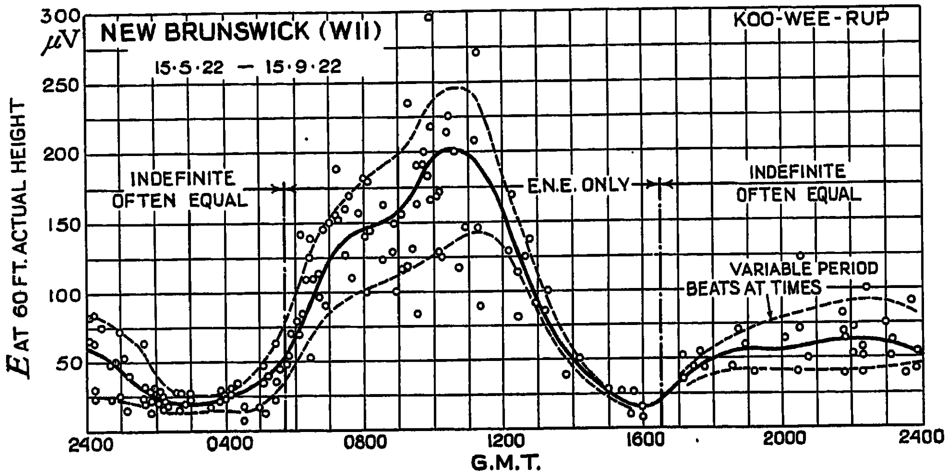

Fig. 46.

Note: Effective height = 12 metres.

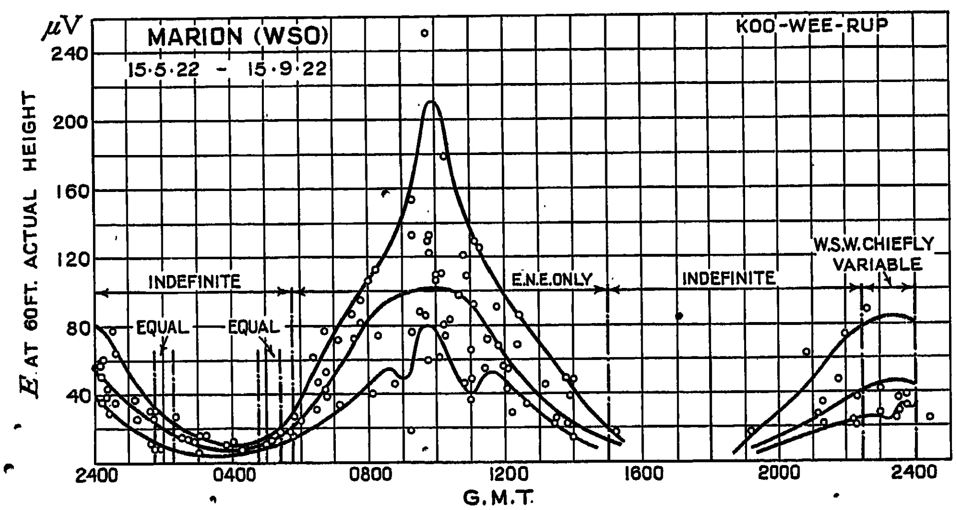

Fig. 47.

Note: Effective height = 12 metres.

with an increase or decrease of signal strength due to interference effects.

Day and Night Variations.

Fig. 80 gives typical curves of day and night variations. Generally speaking, it may be said that the all-daylight signals approximate to a straight line, provided that the daylight extends over a long enough period. When the hours of daylight become less, this straight line, as shown in Fig. 80, becomes a curve having a peak value at about midway between sunrise at one station and sunset at the other station. In the examples shown this is about half way between sunrise at the European station transmitting and sunset on the S.S. "Boonah."

There is always a minimum of signals at the times when it is half light and half dark between the transmitting and receiving stations. The minimum value reached by the signals at these times varies from day to day, but in some cases appears to be fairly constant. The all-dark values are very variable, and although it may generally be said that the all-dark signals at some time during the night will usually be greater than the

daylight signals, there are certain stations from which, at certain places, the average all-dark signal is consistently less than the all-daylight signal. There are some cases, e.g. Honolulu and San Francisco at Melbourne (Figs. 48 and 49), in which there is almost invariably a peak connected with sunrise at the transmitting station, and there are also examples of peaks of regular occurrence on other stations which appear to be connected definitely with sunrise at the receiving station; but as regards the all-dark period there appears to be nothing in any way definite, except possibly at very great distances such as the reception of the European stations at Melbourne, where it may be said there will always be a peak value at the all-dark period. At this distance, however, this period can hardly be termed an all-dark period, as sunset at the transmitting station is followed very shortly by sunrise at Melbourne, and conditions in this case do not appear to have time to become so unsettled. Although smooth curves have been drawn in most cases for these peak values at Melbourne and Perth, giving an average value over a long period of observations, more or less definite

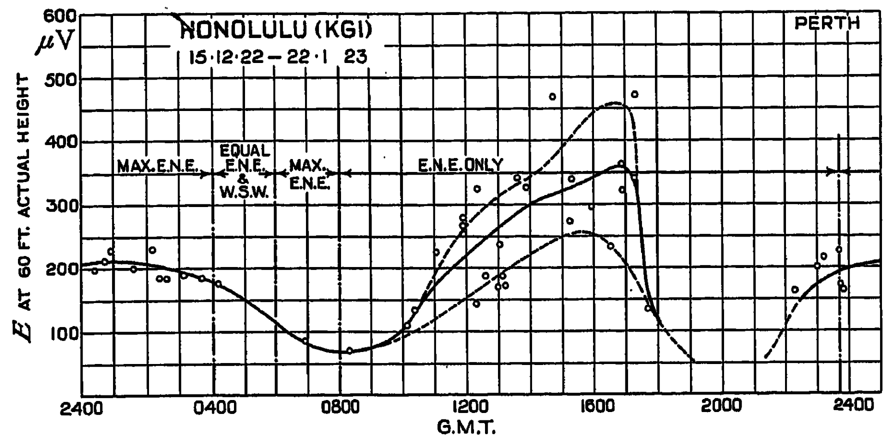

FIG. 59.

NOTE: Effective height = 12 metres.

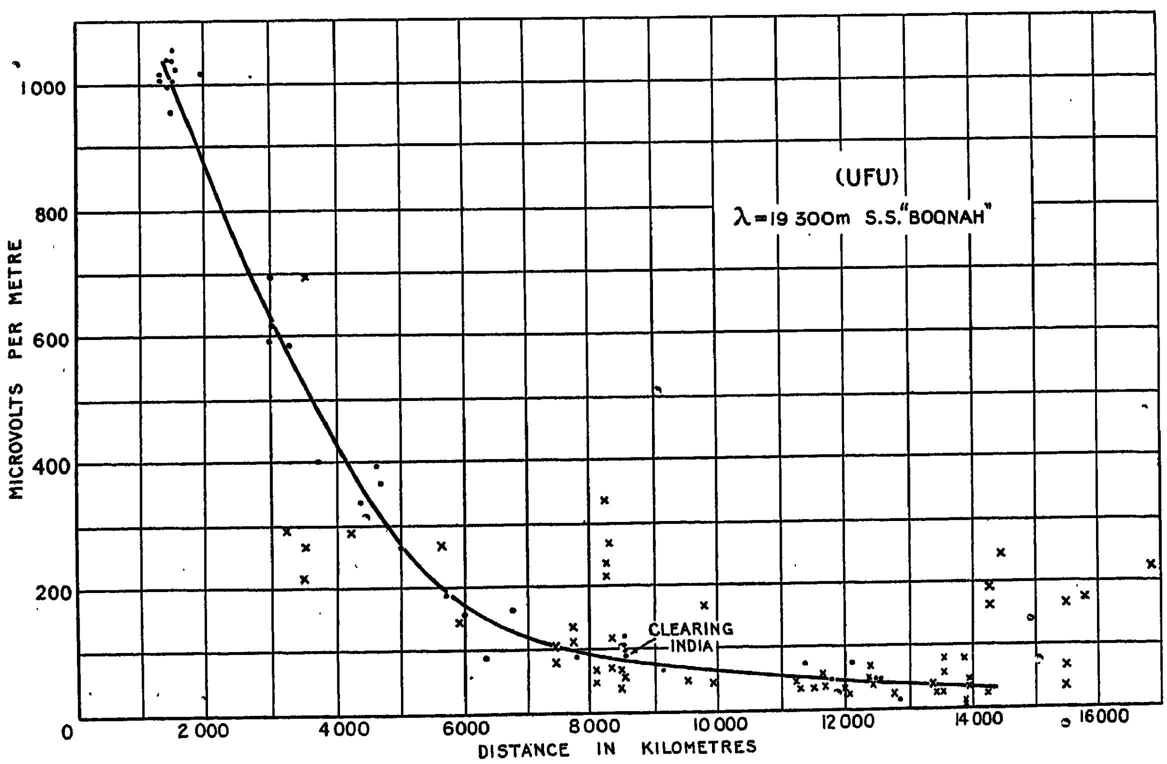

FIG. 60.

variations do occur during these peak times and may be attributed to local effects due to sunrise and sunset at the transmitting or receiving stations.

Effective Heights.

The effective height of the aerial on the S.S. "Dorset" was obtained both by calculation from the actual

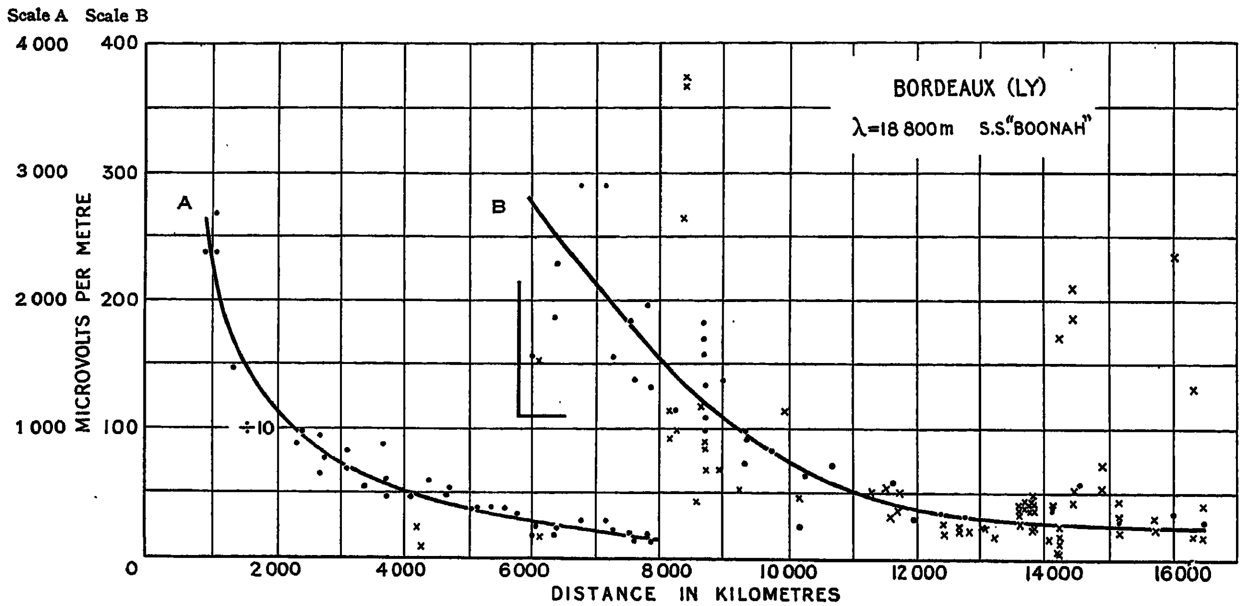

Fig. 61.

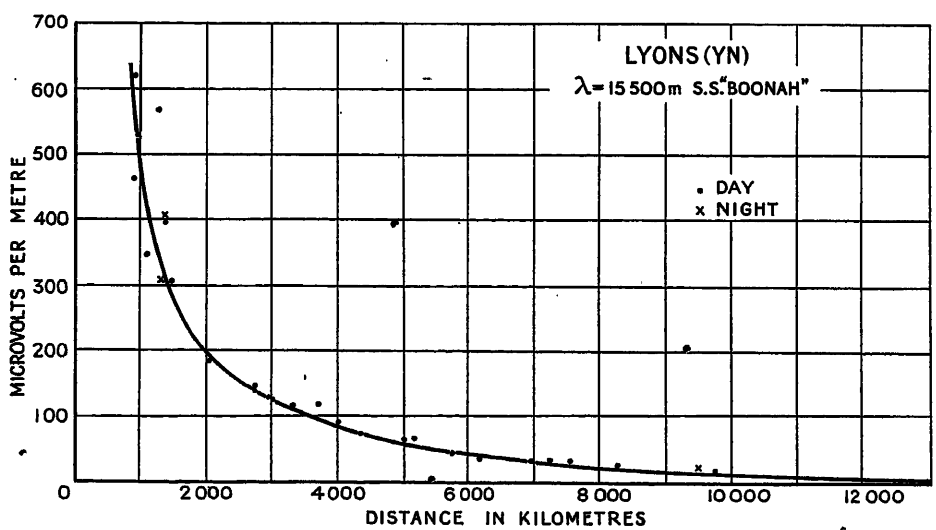

Fig. 62.

dimensions of the aerial, and also by a comparison of values of E.M.F. obtained of signals from the New York stations in the Irish Channel simultaneously with values obtained at Chelmsford, allowing for the absorption over England, the value of which had previously been found from tests made at Towyn, Poldhu, Girvan and Chelmsford. This effective height was taken as 12 m.

At Melbourne and Perth the aerials used were similar to an aerial of which the effective height had previously been obtained by experiment at Chelmsford. In these cases the height was again 12 m.

On the S.S. "Boonah" the effective height was obtained by calculation from the aerial dimensions, and also by a comparison of the E.M.F.'s measured on signals from the various stations with the values measured on shore at Melbourne, Perth and Poldhu, the S.S. "Boonah" being near these places on the homeward voyage. In the case of Poldhu, the American stations were used for the comparison. A value of 17·6 m was obtained for this aerial.

All distances on the voyage from Liverpool to Auckland have been worked out by Mr. Cunningham, Senior Wireless Officer of the S.S. "Dorset," and those on the

return voyage by Mr. Allnutt, who assisted in all experiments on the expedition.

Atmospherics.

Atmospherics were observed to be of two main types —clicks and crashes. The former have a sound similar to that produced in a receiver by a single lightning flash. Crashes may be of any duration from, say, 0·5 second to 5 seconds. The longer crashes lasting for several seconds appear to be connected with local temperature changes and squally weather, and were observed at Melbourne in the spring and autumn.

The term "grinders" has been applied to the continuous atmospherics noted chiefly in or near the tropics during the afternoon. Although there has been a tendency in the past to treat grinders as a type of atmospheric distinct from clicks and crashes, there is no doubt that these grinders are merely a very great number of clicks and crashes occurring together over a large area.

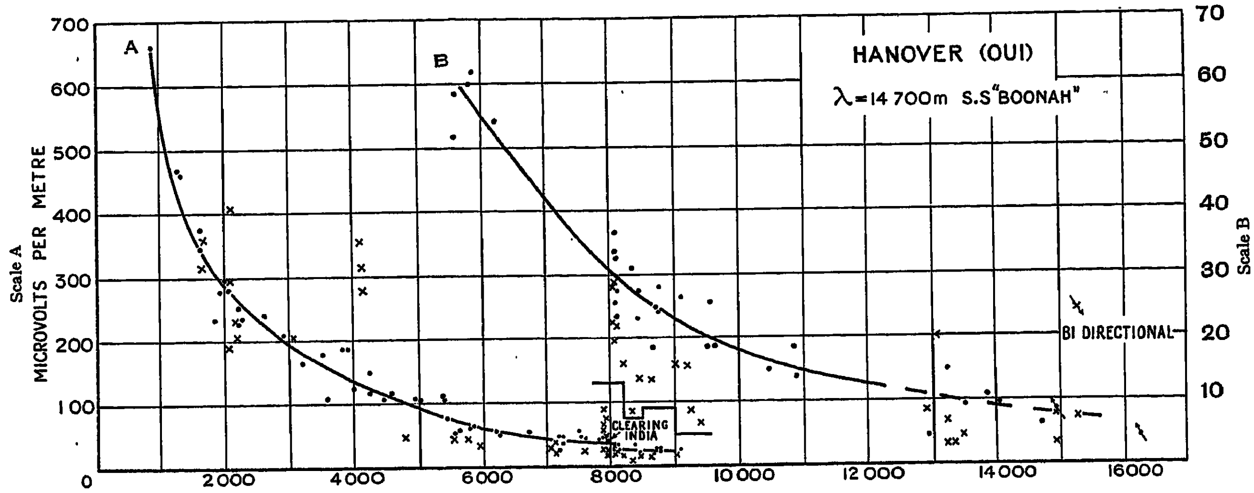

Fig. 63.

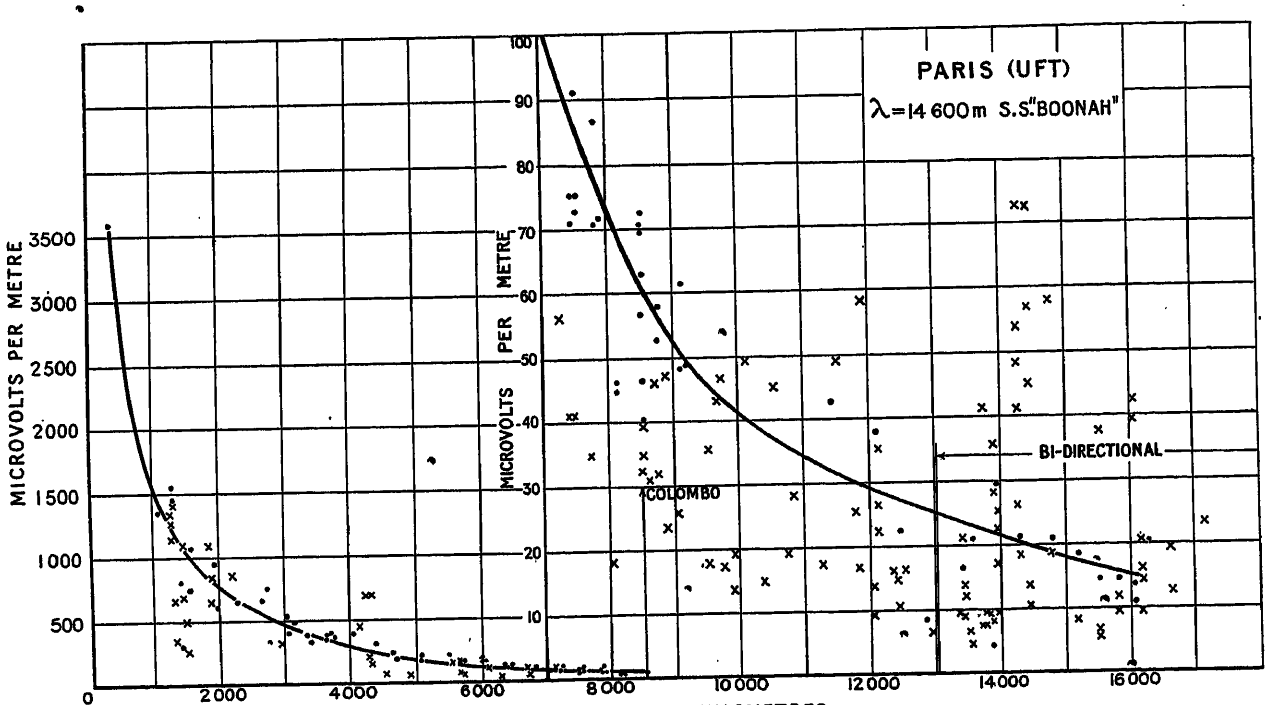

Fig. 64.

There is one other quite distinct type of atmospheric known as "fizzly" which often accompanies rain and hail squalls. This type produces a continuous hissing sound in the receiver, and is only present when showers of rain or hail having charged particles are near or actually in contact with the aerial.

It was found that, apart from purely local storms which may occur in any part of the world from day to day and at any time of the day, atmospherics were always produced over large areas of land in or near the

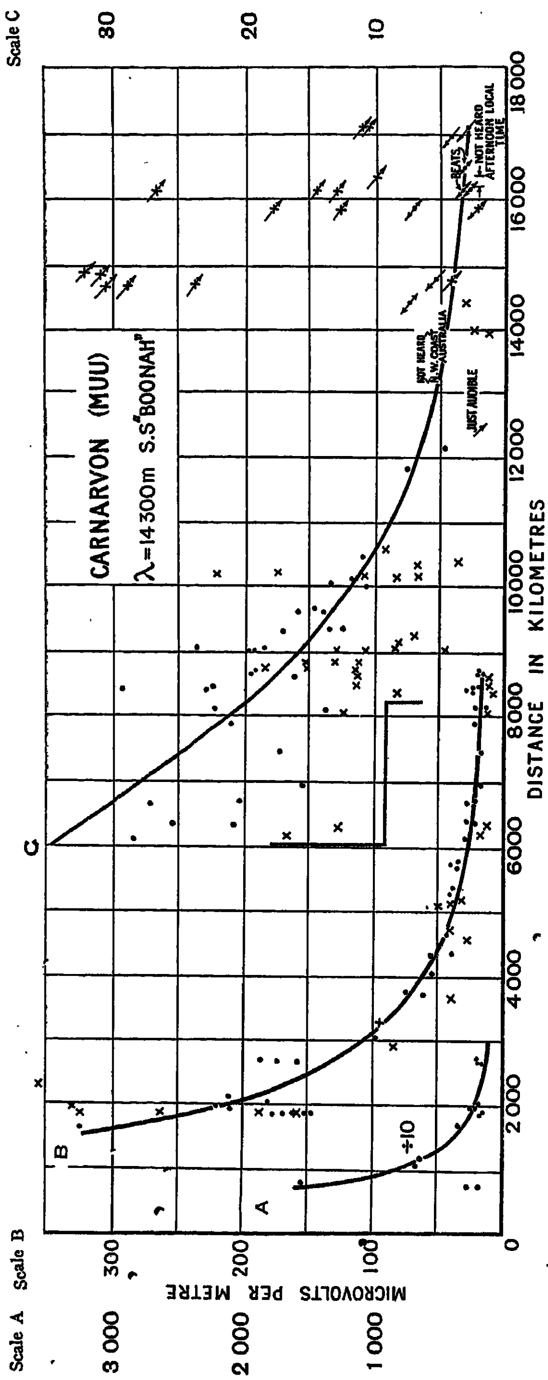

Fig. 65.

tropics. The number of these atmospherics produced over these land areas reached a maximum at about 3 p.m. local time at any place in those areas, the numbers decreasing towards sunset, reaching a minimum in the early hours of the morning and increasing again to the maximum about 3 p.m., when continuous atmospherics or "grinders" were heard. The place of origin of these grinders was observed to vary with the seasons, being in the Northern hemisphere during the summer in that hemisphere, and in the Southern hemisphere during the summer in the Southern hemisphere. During the Northern summer these grinders are mostly produced in Northern Africa, Arabia, India, Burma, Siam, the South of China, Mexico, and South America North of the equator.

During the summer in the Southern hemisphere the majority of the grinders originate in Southern Africa, Australia and South America. The numbers produced appear to be proportional to the area of the tropical land, and no grinders are produced over the oceans.

On the homeward voyage of the S.S. "Boonah," during the summer in the Northern hemisphere, a large number of bearings were taken showing very clearly the movement of these grinders westward with the sun. The bearings shown on each map were all taken at about the same G.M.T. on various days during the voyage and have been corrected for the great circle. All the bearings in Fig. 81 were taken between 0700 and 0800 G.M.T. and show the origin of the "grinders" to be in Southern China when it is about 3 p.m. there. The clicks at this time are only few in number and indefinite in the Mediterranean where it is early morning, but are increasing in numbers in Persia and Northern India with the approach of the grinders, which are seen at their 3 p.m. maximum in Afghanistan some three hours later (see Fig. 82).

By this time the clicks are decreasing in numbers in Southern China after the passing of the grinders' maximum there. Fig. 83 shows the conditions some three hours later when the grinders in Northern Africa are at their height, and Fig. 84 some seven hours later shows the grinders' origin in the North of South America and Central America. It is not easy to observe the South American grinders until the decrease with night of the clicks and crashes from Northern Africa, which, at this time of the year, is an enormous atmospheric-producing centre. After the American grinders there are no more produced until 0700–0800 G.M.T., when the cycle is repeated, commencing again with Fig. 81, this absence of grinders from about midnight until 0700–0800 G.M.T. being due to the absence of land areas in the Pacific Ocean.

Bearings obtained on the grinders at Melbourne and Perth during the Australian summer intersected about the centre of tropical Australia, as shown in Fig. 81, during the afternoon there. These Australian grinders became less and less towards sunset, the clicks and crashes forming them becoming less and less in number during the night and finally reaching a minimum about sunrise. With the diminution of these Australian grinders, a further series of grinders was heard from the direction of South Africa (see Fig. 83), reaching a maximum frequency about 3 p.m. local time in South Africa.

The results just described were obtained during December–February at Perth and Melbourne. Between midnight and 0700 G.M.T. small continuous atmospherics were frequently observed at Melbourne in a South-

Easterly direction, and there is not much doubt that these atmospherics originated in the North of South America. These South American atmospherics were less in numbers than at their 3 p.m. maximum some hours previously, but became more noticeable at Melbourne with the increase of darkness between Melbourne and South America over the Pacific. It was found that atmospherics increased in strength with darkness in the same manner as signals, and in several instances there appeared to be fading periods on atmospherics at a time when half-light and half-dark conditions intervened between the receiving station and the source of the atmospherics. This fading would not be as marked as that on the signals, due probably to the fact that the atmospherics originated over a large area and would not all reach a minimum at the same time.

than on the shorter wave-length of, say, 10 000 m. This fact was an additional aid in the separating of the various sources. In the same manner, at times at Perth when the Australian atmospherics and the longer-distance African atmospherics were present simultaneously, a bearing taken on atmospherics on 10 000 m would be North-East and one taken on 20 000 m would be South-West, the near-by atmospherics predominating on the shorter waves, and the longer distance predominating on the longer wave-lengths. Generally speaking, a lengthening of the wave-length enabled atmospherics to be heard from over a larger area. The bearing on the unidirectional receiver on a near-by atmospheric-producing centre covering a large area was always less definite than that on a similar source at a great distance; and the most difficult conditions for observations were when

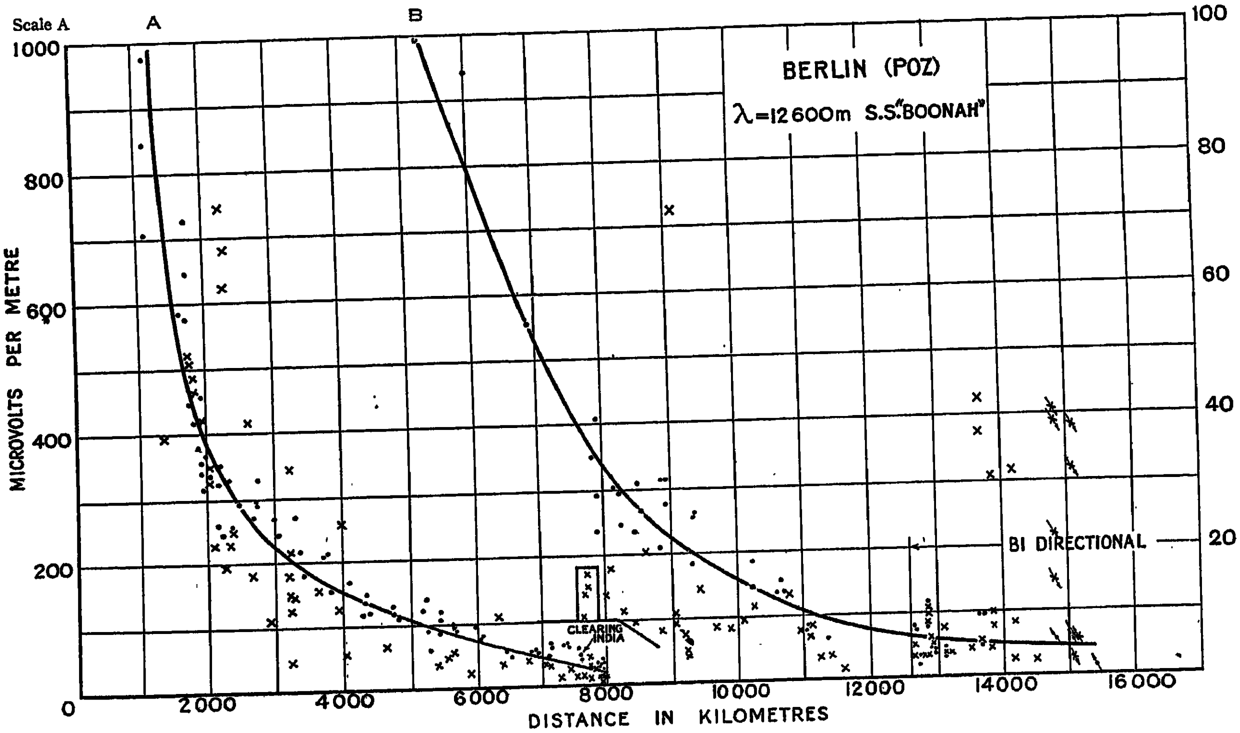

FIG. 66.

These South American atmospherics heard at Melbourne, being opposite in direction to those from the Australian Continent, were difficult to distinguish from the latter on the unidirectional receiver, as on rotating the moving coil of this receiver to what would be the minimum of one source of atmospherics, atmospherics from the opposite source are received at maximum intensity, or, in other words, there is no minimum obtainable at any position of the rotating coil. This also applies to the African atmospherics received at Perth. The existence of the two sources may, however, be proved by the fact that the bearing or minimum on the frame or bi-directional receiver is very marked at these times, whereas the bearing or minimum on the unidirectional receiver is almost non-existent. These atmospherics received from great distances were always more marked on the long wave-lengths of the order of 20 000 m two sources were present simultaneously in directions at right angles. Under these conditions it was only possible to distinguish the two sources by some difference in the sound or the frequency of the atmospherics from the two sources. The maximum intensity of the African atmospherics received at Perth was found to be some two or three hours after their maximum frequency at 3 p.m. in Africa, or at a time when darkness extended between Perth and Africa.

Information regarding the microvolts per metre required to read through atmospherics in various directions was obtained on the unidirectional receiver at Melbourne and Perth, and also by another expedition in South America, and ratios were obtained of these readabilities in various directions at different times of the day. These results have not been published in this paper. In similar work carried out by the

FIG. 72.

expedition to South America, the African and South American sources of atmospherics were very clearly marked. This expedition recorded local origins of atmospherics in the mountains near Rio. In Australia, on occasions, the mountains of the Dividing Range

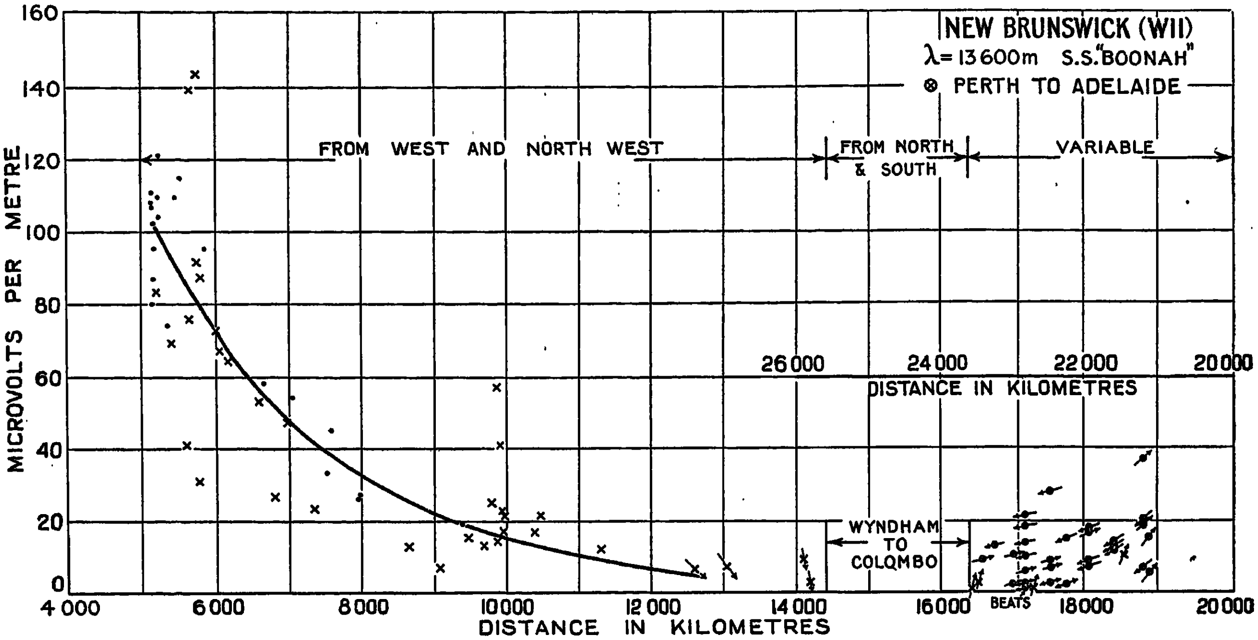

FIG. 73.

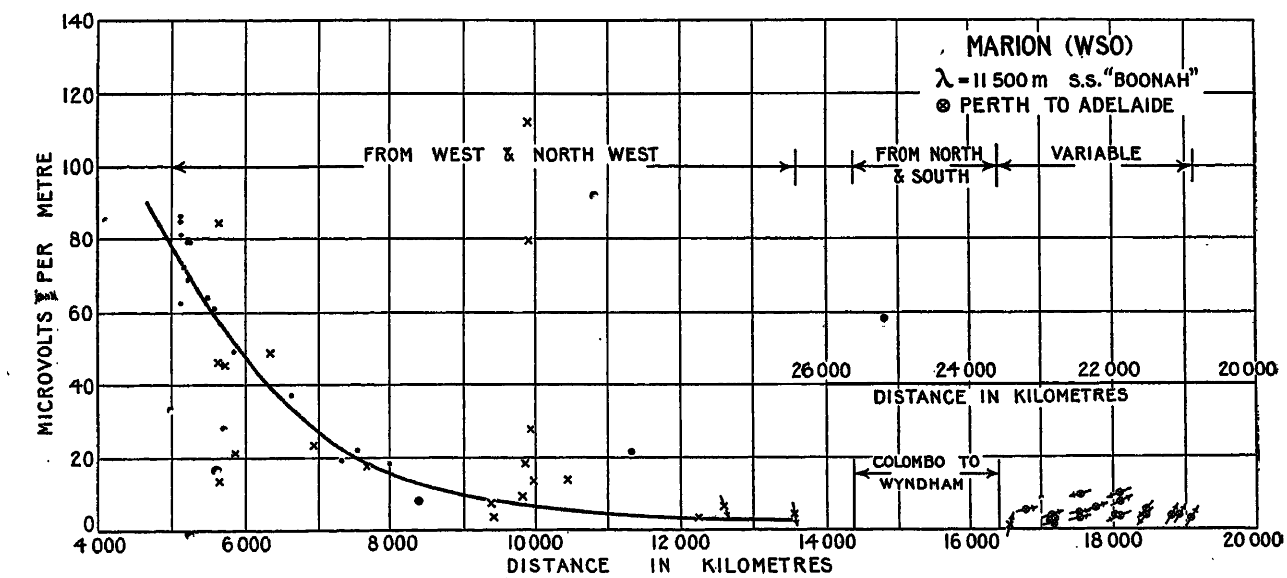

FIG. 74.

in the neighbourhood of Sydney appeared to be the origin of bad local clicks. These local clicks were also observed in the neighbourhood of Java on the return journey, and in the neighbourhood of the Abyssinian mountains, both of which districts are known to be thunderstorm centres. It was found in general that a local thunderstorm did not affect the readability of weak signals to the same extent as near-by grinders. Whereas in the former case letters would only be obliterated at intervals by lightning flashes, in the latter case all traces of the signals would often be entirely buried by the continuous grinders. Local storms at Melbourne appeared to be most prevalent during the spring and autumn at the change of seasons, and their effects were superimposed on the regular diurnal changes occurring in the grinders, differing from the latter in that they might occur at any time and in any direction.

Figs. 85 and 86 show the diurnal variations in the bearings of atmospherics as noted at Rio de Janeiro by the party observing there, and by the Australian party at Melbourne and Perth. These bearings are for the month of February when the sun is in the Southern hemisphere. At midnight G.M.T., 3 p.m. local time in the Pacific, there is no grinder maximum, and there are the remainder of the clicks at the South American centre and a few from the African centre. In Australia the clicks from the local centre are very few due to its being early morning there, and the remainder of the African clicks from the whole of that centre received at Perth and Melbourne as small continuous clicks are decreasing with the extension of daylight over the Indian Ocean.

At 0300 G.M.T. the production of atmospherics is at a minimum in Africa with sunrise there, and nothing is heard from the latter centre either in Australia or Rio. In Australia the clicks are increasing with the approach of 3 p.m., and at this period small continuous atmospherics are frequently observed from the direction of South America where the clicks are still in evidence.

At 0600 G.M.T. the Australian grinders are at their maximum. The small continuous clicks are still audible from the South American centre as darkness extends over the Pacific, but these clicks are becoming less with the approach of sunrise in South America, until finally at sunrise there, at 0900 G.M.T., they disappear. By this time the grinders are becoming less in Australia and are commencing in Africa. By 1200 G.M.T. the Australian grinders are decreasing and thinning out into less and less continuous clicks, and the small African grinders, which by this time are near their frequency maximum, become noticeable in Australia and Rio. At the same time the clicks are increasing at the South American centre. At 1500 G.M.T. rather similar conditions prevail, but the Australian clicks are fewer though of greater intensity due to night propagation; the African grinders are of greater intensity also due to the increase of darkness, and the South American clicks are developing into grinders which reach a maximum about 1800 G.M.T. The African grinders are now less in numbers but at their maximum intensity in Australia, due to its being dark all over the Indian Ocean. By 2100 G.M.T. the Australian clicks are at their sunrise minimum of production, the African small continuous atmospherics are still in evidence, and the grinders at the American centre are decreasing. The latter are not yet noticeable at Melbourne, due probably to the fact that it is daylight all over the Pacific.

Attenuation.

In developing a theory to explain this mass of material, the variability of the data should always be borne in mind.

It is not possible to say that the signal strength at a given place will remain constant even when all the known factors, such as aerial transmitting current, effective height, nature of the intervening ground, etc., remain constant.

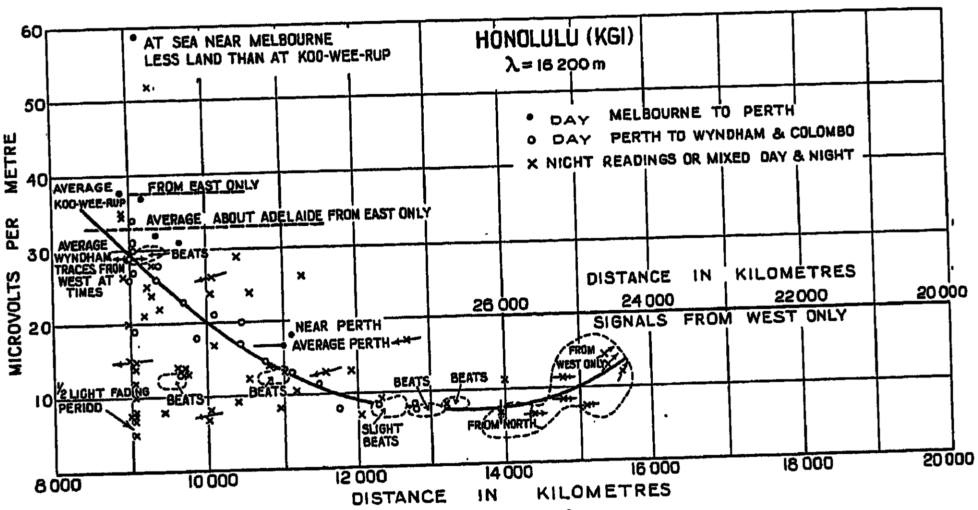

FIG. 75.

Apart from the more or less regular diurnal changes, there are accidental changes which may in certain cases amount to a large fraction of the mean E.M.F. to be measured.

This accidental variation is, as is well known, especially great when the ray lies entirely in the dark hemisphere, and for this reason it is necessary to obtain a very large number of night readings before they can be reduced to order. As it was impossible to keep a regular 24 hours' watch on the trip, the night readings obtained must be regarded merely as samples from which only little information can be obtained.

Day readings, on the other hand, are very much steadier, and although at great distances there is a very marked diurnal change (even when the ray is wholly in light), isolated values do not vary from the mean to an extent comparable with the night readings. In general the mean day value will be chosen for comparison with the

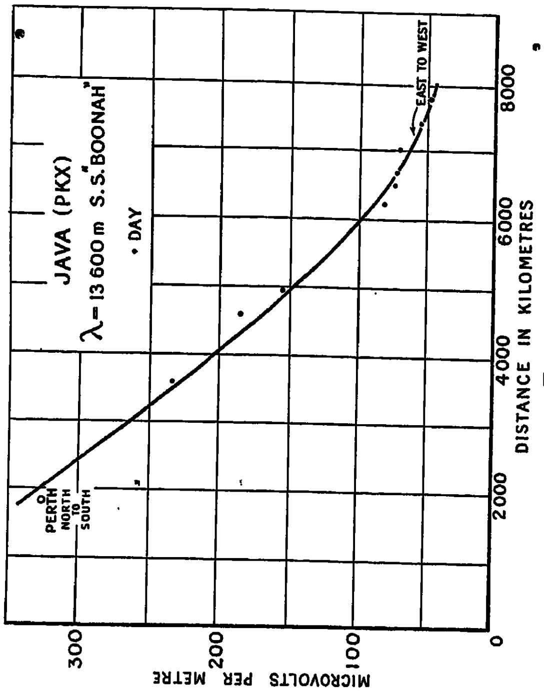

FIG. 77.

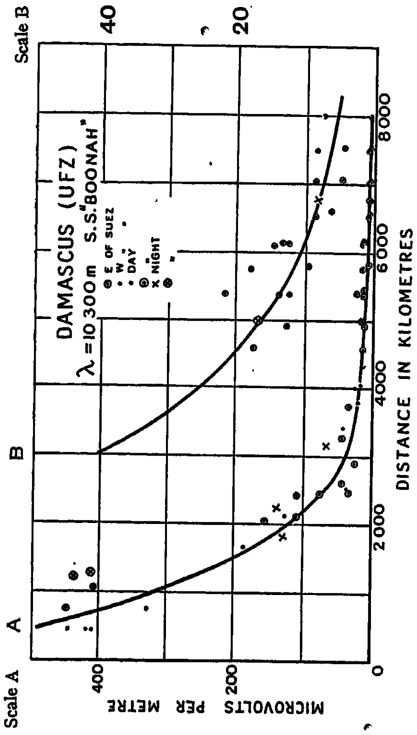

FIG. 79.

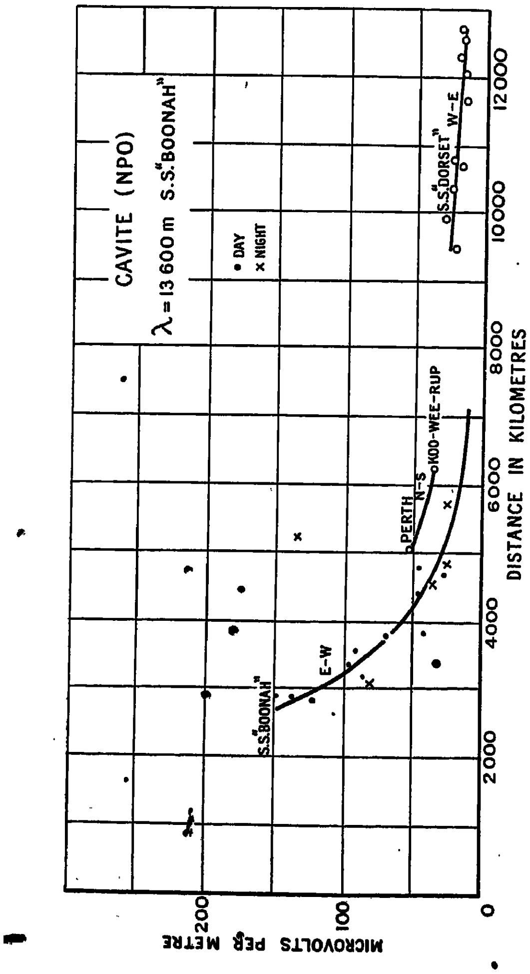

FIG. 76.

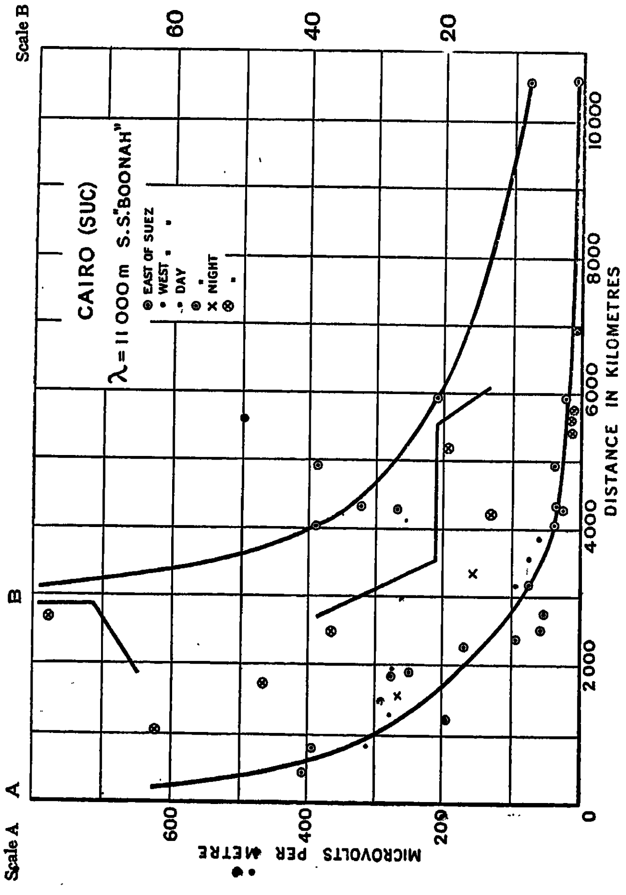

FIG. 78.

theoretical value, except where otherwise explicitly stated. It is well to emphasize the fact that isolated observations should be viewed with distrust.

In the case of the attenuation curves the values taken from a smooth curve passing through all the day readings will constitute the observed value. A certain amount of latitude in drawing the smooth curve is possible, of course, but the accuracy of the results does not warrant any elaborate mathematical process for determining this mean curve exactly, and the labour entailed would be prohibitive.

Choice of comparison formulæ.—In our opinion there does not seem to be very much doubt about the choice of formula for comparison.

Although Austin's formula, which expresses the signal E.M.F. in the form

$$E \text{ (in volts per cm)} = \frac{120\pi h I e^{-\alpha d/\sqrt{\lambda}}}{\lambda d}$$

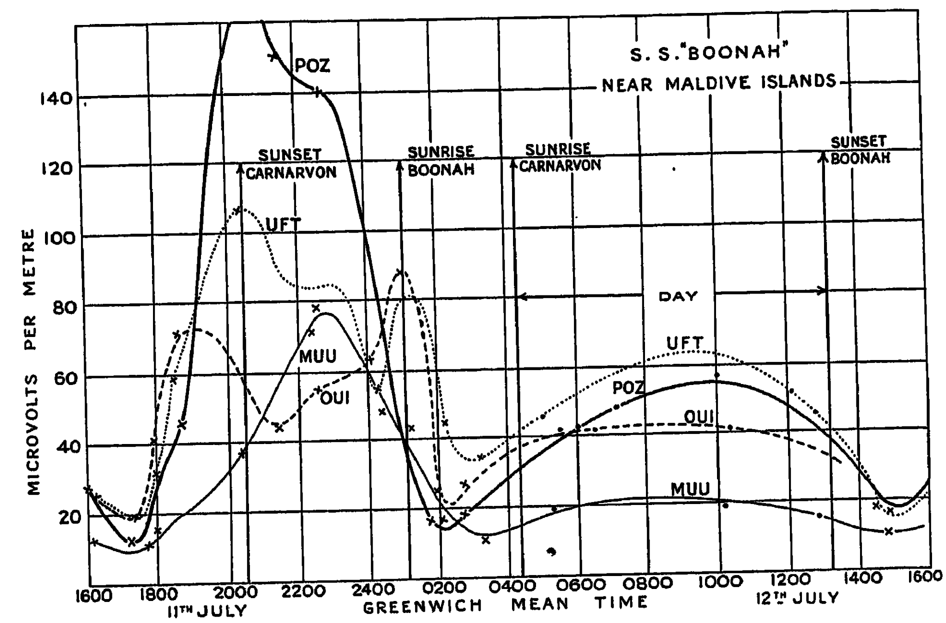

FIG. 80.

has received the sanction of use, it is admittedly of a semi-empirical nature, and although it might be useful as a means of calculating signal E.M.F.'s it can give no information with regard to the nature of the transmission of signals, beyond the fact that it either agrees or does not agree with the observed facts. On the other hand, we have in the work of G. N. Watson two very explicit formulæ, which we may call the diffraction and reflection formulæ respectively, from which a great deal of information may be derived. These two formulæ enable one to calculate the observed E.M.F.'s in the ideal case of a transmitter situated on the surface of the earth and sending signals to a receiver at any other point, (*a*) when there is assumed to be no reflecting layer, and (*b*) when there is assumed to be a well-defined reflecting layer.

The comparison of the observed results with these formulæ will give information regarding the nature of the transmission, for it will be shown that the values derived from (*a*) fall short of the observed results, and we must therefore abandon the hypothesis that the waves travel round the earth without the aid of a reflecting layer, and compare the results with the formula (*b*) to see how nearly the assumption of a well-defined reflecting layer is justified.

The formulæ in question are :—

(*a*) *Diffraction formula.**

$$E \text{ (in volts per metre)} = \frac{0\cdot5365 I h e^{-23\cdot9\theta/\lambda^{\frac{1}{3}}}}{\lambda^{\frac{7}{6}} (\sin\theta)^{\frac{1}{2}}}$$

where h = effective height of the transmitter (in km),
λ = wave-length (in km),
I = transmitting current,
θ = zenith angle between transmitter and receiver.

(*b*) *Reflection formula.*—The absolute value of this is not given by G. N. Watson, but he shows that the E.M.F consists of terms of the form

$$\frac{AhIe^{-\alpha d/\sqrt{\lambda}}}{\lambda(R\sin\theta)^{\frac{1}{2}}}$$

where d is the distance ($R\theta$) and the other quantities are as given in the previous formula, and

$$\alpha = \frac{1}{2H}\left\{\left(\frac{\mu_1\rho_1}{2c}\right)^{\frac{1}{2}} + \left(\frac{\mu_2\rho_2}{2c}\right)^{\frac{1}{2}}\right\}$$

ρ_1 = resistivity of the upper layer,
ρ_2 = resistivity of the earth,
H = height of layer above the earth,
c = velocity of light,
μ_1 = permeability of upper medium, and
μ_2 = permeability of earth.

FIG. 86.

Comparison with diffraction formula.—The theoretical values derived from (*a*), the diffraction formula, are on some of the curves in Figs. 17 to 30, as well as the actual values obtained on the S.S. " Dorset " in the Atlantic.

The absolute values depend on the assumed values of the effective height and transmission currents of the sending stations. The values assumed are given in Table 10. In some cases the assumed values of the effective height may be open to a certain amount of doubt, but they are not likely to be more than 15 or 20 per cent in error. In any case this doubt does not affect the main result, that at distances greater than about 2 000 km diffraction alone is wholly inadequate to explain the observed results. At smaller distances, however, the observed and calculated curves are in better agreement, and at 300 or 400 km distance the observed values are only slightly in excess of the calculated ones.

These results, as before stated, drive us to the assumption of some form of reflecting layer. The effect of reflection, it would appear, begins to be important at distances of about 700 km, and at distances greater than about 2 000 km the effect of diffraction alone is wholly insignificant and Watson's second expression, i.e. the reflection formula, should be applicable.

Physical meaning of formula.—Before describing the results of this comparison, it would be well to make a digression and explain the physical meaning of Watson's second formula, given in (*b*) above.

The similarity between this and Austin's formula is very great. The exponential factor is of the same form, but the factor $AIh/[\lambda(R \sin \theta)^{\frac{1}{2}}]$ is different in respect of the denominator, which is proportional to $(\sin \theta)^{\frac{1}{2}}$ in Watson's formula.

The radiated energy, which is proportional to E^2, varies as $1/(R \sin \theta)$ in the Watson formula, and as $1/(R^2 \sin^2 \theta)$ in the Austin formula, where, since it varies inversely as the square of the distance, it represents a spherically expanding wave. In the former case the radiated energy, except for the exponential factor, varies inversely as $R \sin \theta$. This is the appropriate factor for the transmission of energy between two circular shells. The intersection of these by a cone of angle θ will form a ring of area $2\pi HR \sin \theta$ through which the energy must be radiated, and since the energy flow per unit area is $A/(R \sin \theta)$ the total flow through any two such rings, namely

$$\frac{A}{R \sin \theta} 2\pi HR \sin \theta$$

is constant, except for the loss represented by the exponential factor.

With regard to the attenuation factor, this, it will be observed, is of the same form as in Austin's formula, but the attenuation constant α in Watson's formula, instead of being an empirical constant, is a function of the resistivities of the two layers and the distance between them. The greater the resistivity of either, the greater is the attenuation. On the other hand, the greater the distance apart of the layers the less is the attenuation. This is because the energy is not frittered away so quickly when the distance between the layers is large, so that there is more energy to draw from.

It is interesting to note that a plane, or approximately plane, wave travelling between two flat surfaces which are the same distance H apart, and of the same resistivities ρ_1 and ρ_2, suffers the same attenuation as the above.* It follows that the slight curvature of the earth's surface has no perceptible effect upon the attenuation; the bounding walls merely act as guides and take their quota of energy independently of their curvature.

To sum up, Watson's formula expresses the fact that the energy is guided between the inner and outer sphere and is attenuated on account of the loss in the bounding walls, this attenuation to the first approximation at least being independent of the curvature of the surfaces.

To put the expression in a form suitable for calculation, we have assumed that E can be expressed in the form

$$E = \frac{120\pi hIe^{-\alpha d/\lambda^{\frac{1}{2}}}}{\lambda(d_0 R \sin \theta)^{\frac{1}{2}}}$$

in which the interference due to the several terms in Watson's expression has been neglected, for reasons

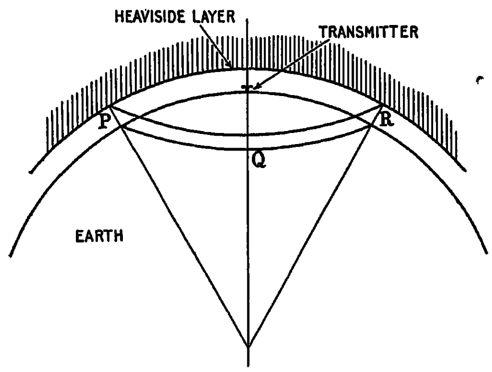

FIG. 87.

to be given later, and in which the semi-empirical distance d_0 has been introduced. The quantity d_0 must be of the dimensions of a distance to fit in with the other dimensions of the formula. If all the energy emitted is assumed to be radiated uniformly through any annulus PQR (see Fig. 87) the distance d_0 will be $3H/2$, where H is the height of the layer.

For the energy radiated is

$$\frac{40(2\pi)^2 h^2 (I_{\text{r.m.s.}})^2}{2\lambda^2}$$

Also the energy radiated through the annulus is $\frac{E^2}{4\pi c}$ ergs per unit area, or $\frac{E^{2} 10^{-7}}{4\pi c}$ watts. The area of the annulus is $2\pi HR \sin \theta$, i.e. the energy radiated through the annulus is

$$\frac{E^2 \times 10^{-7} R \sin \theta}{2c}$$

* The extension of a piece of analysis by J. J. THOMSON in " Recent Researches in Electricity and Magnetism."

Equating the two we get:

$$E = \frac{120\pi h I}{\lambda[(3/2)HR \sin \theta]^{\frac{1}{2}}}$$

and $d_0 = 3H/2$, neglecting the absorption factor.

The value of d_0 so obtained is obviously too small, since it assumes that the whole of the energy arrives at OPQ, and it is probable that the energy radiated almost vertically near the transmitter will escape or be lost in the semi-conducting layer.

Comparison of the Observed Results with Formula.

The procedure is as follows: The value of E, the signal strength in microvolts per metre, for every 500 km is taken from the smooth curve, and the logarithm of this is added to the logarithm of $(R \sin \theta)^{\frac{1}{2}}$ for this distance. If E is of the form

$$E = \frac{120\pi I h e^{-\alpha d/\lambda^{\frac{1}{2}}}}{\lambda(d_0 R \sin \theta)^{\frac{1}{2}}}$$

then $\log (R \sin \theta)^{\frac{1}{2}} + \log E = \log \left(\frac{120\pi h I}{\lambda (d_0)^{\frac{1}{2}}}\right) + \frac{-\alpha d}{\lambda^{\frac{1}{2}}}$.

This quantity plotted as a function of d should be a straight line, the slope of which is $-\alpha/\lambda^{\frac{1}{2}}$. The value of λ being known, it is possible to determine the value of α.

The results at great distances are complicated by transmission both ways round the world, as described in the earlier portion of this paper, but this effect should not be appreciable at distances less than about 12 000 km. We may take 10 000 km, or one-quarter of the circumference of the world, as a safe limit.

It will be obvious from even a casual glance at the attenuation curves obtained on the voyages of the S.S. "Dorset" and "Boonah" that the attenuation varies from place to place and may even vary with the direction of transmission. In view of this the instantaneous value of α, i.e. the slope of the curve, should be plotted as a function of the distance for all distances.

Owing to the variability of the data, however, the mean values of the slope for distances less than about 2 000 km are very ill determined, so that it is necessary to take the mean value of the slope over at least 4 000 or 5 000 km before a reliable determination of α can be made. Another source of confusion is the fact that the total attenuation may not be a function of the distance alone but may vary with the direction of the ray. For instance, if the course of the ship is inclined at an angle to the great circle joining the ship and the transmitting station under consideration, the change of signal strength with distance does not necessarily give the "instantaneous value" of α but also includes the change of the "mean value" of α with the direction of the ray. In view of these considerations the observations on the voyage of the S.S. "Dorset" have been divided into three parts, in each of which the values of α appear to be sufficiently constant to determine it fairly accurately. The first group comprises those observations taken on the Atlantic voyage, i.e. from Liverpool to Newport News; the second those on the voyage between Newport News and Panama, and the third those between Panama and New Zealand, but excluding those that were taken at distances greater than about 12 000 km from the transmitter. During the Atlantic voyage the course of the ship followed approximately the direction of the great circles from the transmitting stations, so that the results should not be complicated with the variations caused by changing ray directions. At the same time the rays were practically wholly over sea, and the effect of land absorption should be practically absent.

The actual mean values of α have been determined for the 10 stations given in Table 7.

TABLE 7.

European Stations.

Station	λ	α
	km	
Bordeaux (LY)	23·45	0·00223

Nauen (POZ)	12·6	0·00144
Stavanger (LCM)	12·0	0·00181
Rome (IDO)	11·0	0·00158
Clifden (MFT)	5·8	0·00193

Mean $= 0{\cdot}001802 \pm 0{\cdot}000112$
$= (1{\cdot}8 \pm 0{\cdot}112) \times 10^{-3}$

American Stations.

Station	λ	α
	km	
Rocky Point (WQK) ..	16·45	0·00135
Tuckerton (WGG)	16·0	0·00133
New Brunswick (WII) ..	13·6	0·00153
Marion (WSO)	11·5	0·00148

Mean $= 0{\cdot}00142 \pm 0{\cdot}000033$

The European and the American stations have been grouped separately because there appears to be a real difference in the mean values of α for the two groups. This difference, 0·00038 (0·00180 − 0·00142), is more than three times the probable error of either group and can therefore be considered to be a real and not an accidental difference due to the uncertainty of the readings.

Apart from this difference, which comes as rather a shock to our preconceived notions of reversibility in optics, and which will be discussed in greater detail later, the value of α is practically independent of the wave-length.

In the curves (Fig. 88) α is plotted against wave-length; except for LY on a 23·45 km wave-length, which has an excessively high value of absorption, the values are very approximately constant.

For transmission across the Atlantic the observed values are in good agreement with a formula of the type

$$\frac{Ae^{-\alpha d/\sqrt{\lambda}}}{\lambda(R \sin \theta)^{\frac{1}{2}}}$$

i.e. a formula of the reflection type; and we may therefore conclude with a fair degree of certainty that transmission takes place in the space between the earth and an upper conducting layer.

The voyage from Newport News to Panama being only about 3 700 km affords no very well-determined ment above must be taken with a certain amount of reserve.

The European stations also show no very marked change of α for this portion of the voyage. The results are included therefore with the previous transatlantic values, and the figures given above refer to the mean

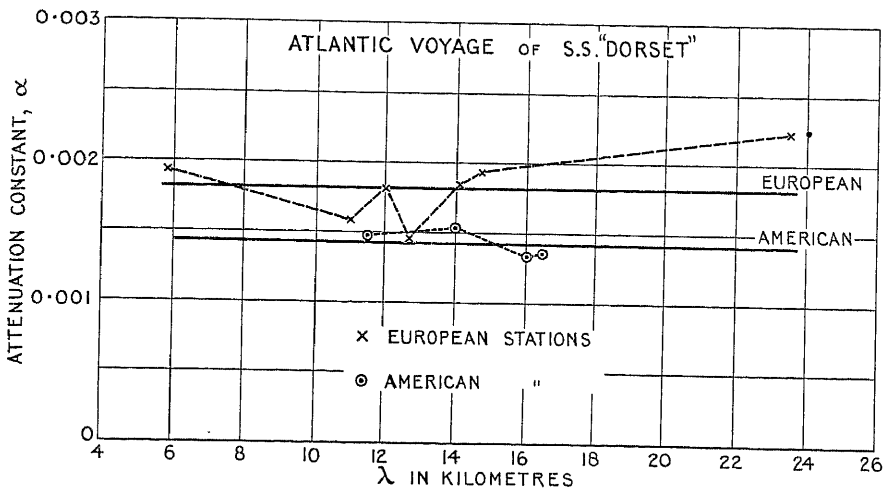

FIG. 88.

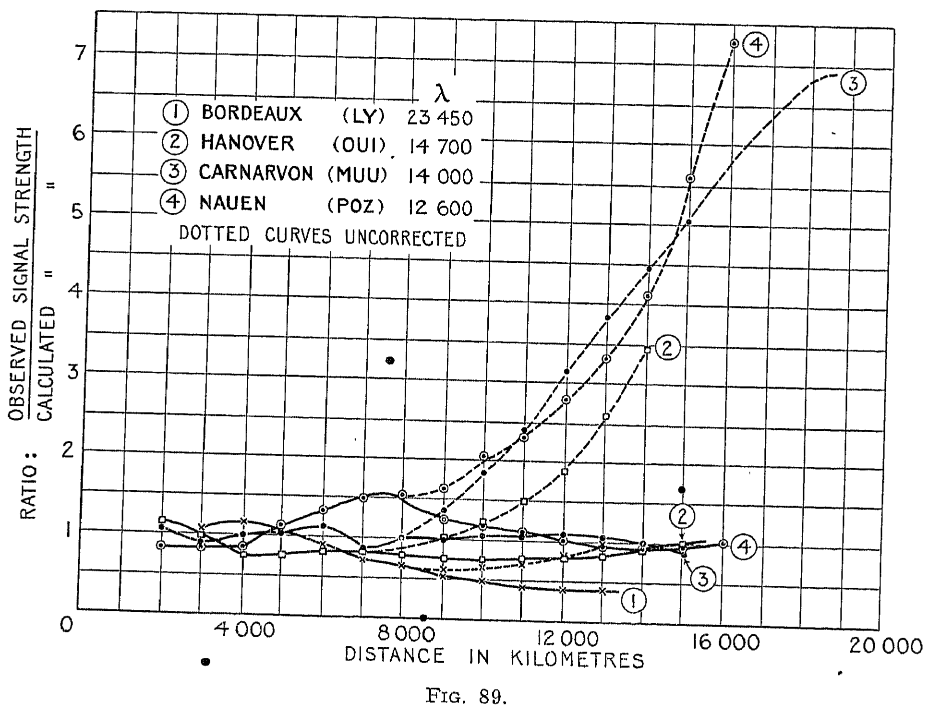

FIG. 89.

values of α. The direction of transmission from the American stations is nearly due South and the points obtained lie close to the curve already obtained for transatlantic transmission. Transmission southwards from the neighbourhood of New York is therefore practically the same as West to East transmission. The distance, however, is hardly sufficient to disclose any small changes in attenuation, so that the state-value for the whole voyage to Panama. The change of angle of the ray from the European stations is only of the order of a few degrees and has therefore little effect on the attenuation.

TRANSMISSION IN THE PACIFIC.

European stations.—The ray from Carnarvon during the voyage between Panama (7 700 km) and Pitcairn

Island (14 000 km) in the Pacific crosses only an insignificant amount of land in the region of the narrow part of Mexico. In direction also the ray remains within the limits traced out by the great circles to New York and to Panama respectively, which include an angle of approximately 10°. This is also approximately true of the other European stations, so that the determinations of attenuation of the European signals for this path should not be complicated to any great extent by the effects of land absorption or variations in the direction of the ray.

On the other hand, the rays from the American stations vary considerably in direction as well as in the amount of land over which they pass. The two groups of stations will therefore be considered separately as before. Unfortunately Stavanger, Rome and Clifden, the shorter-wave stations, dropped out of the observations soon after Panama, the signals being too weak on account of the cumulative effect of absorption on these short waves. Bordeaux, Hanover, Carnarvon and Nauen were the only European ones remaining.

The attenuation constants determined in the manner previously described are given in Table 8.

TABLE 8.

Attenuation in the Pacific.

Station	Wave-length	α	Distance
	km		km
Bordeaux (LY) ..	23·45	0·001243	11 000
Hanover (OUI) ..	14·7	0·000822	11 000
Carnarvon (MUU)	14·1	0·000868	15 000
Nauen (POZ) ..	12·6	0·000890	16 000

Mean value = 0·000955.

The values of α so determined are practically only half those calculated for the transatlantic voyage, a result which is certainly very surprising.

These results are reflected in Fig. 89, in which the ratio of the observed results to those calculated from the formula

$$\frac{120\pi e^{-\alpha d/\lambda}}{\lambda(d_0 R \sin\theta)^{\frac{1}{2}}}$$

(in which α is assumed to be 0·0016) is plotted against distance. Up to a distance of about 8 000 km the agreement is very fairly good, but beyond this the observed values rapidly increase, and at distances of about 15 500 km the observed values may be as much as five or six times the calculated values. If, however, we assume an abrupt change in the attenuation constant at Panama the calculated results for the voyage beyond this will all be much greater, and the curves show that a very fair agreement is obtained if we assume that α is 0·00095 in this region (Fig. 90).

As mentioned before, long-distance transmission takes place in both directions round the world and no doubt part of the relative increase of signals is due to signals coming the other way round the world, but as will be seen later this effect is not sufficient to explain entirely the relatively large signals obtained, and we are driven to the assumption that there is an actual decrease of attenuation in the middle latitudes of the Pacific.

In confirmation of this we may consider the attenuation curves of Darien (NBA) and Cavite (NPO). NBA has rather a short wave (10 000 m) and a high initial absorption, but it steadies after 4 000 km and is nearly constant between 4 000 and 10 000 km, with an attenuation value equal to 0·00115. If we include this first 4 000 km the mean attenuation constant is 0·00138. Whichever value we take, it is considerably smaller than the value 0·00180 for transmission in the Atlantic.

Cavite (NPO) was only measured between 9 000 and 12 000 km and the attenuation constant is not very well determined. It lies between the limits 0·00065 and 0·00082, and certainly upholds the view that the attenuation is small in these regions.

Honolulu (KGI) shows a variation of attenuation with the direction of the ray, signals transmitted in a

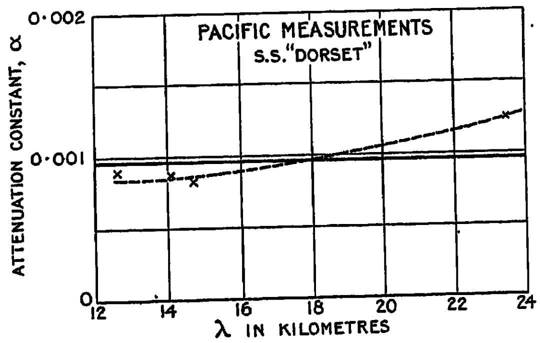

FIG. 90.

South-Easterly direction being stronger than those transmitted to the same distance in a Southerly or South-Westerly direction. The mean attenuation in the South-Easterly direction is 0·00128, but the range is short; in the South-Westerly direction the range is still shorter and no very definite value of α can be obtained.

New York stations.—The transmission of signals from the New York stations in the Pacific is complicated by the effects of varying land absorption and varying ray direction, but they all undoubtedly show a low value of attenuation in the Pacific, i.e. about 0·00114.

RETURN VOYAGE OF S.S. "BOONAH."

The signal strength curves have been shown in Figs. 60 to 70, and these can be treated in the same manner as the observations taken on the S.S. "Dorset," and the attenuation constants determined. In connection with the results of this determination certain broad facts may be noted. In the first place, the measured values of the signal E.M.F.'s of the European stations at great distances, say about 10 000 km or more, greatly exceed those measured on the S.S. "Dorset" at the same distance, in spite of the fact that much of the transmission in the case of the S.S. "Boonah" was overland. At short distances from the transmitting stations the measured values in microvolts per metre agree fairly closely, so that the attenua-

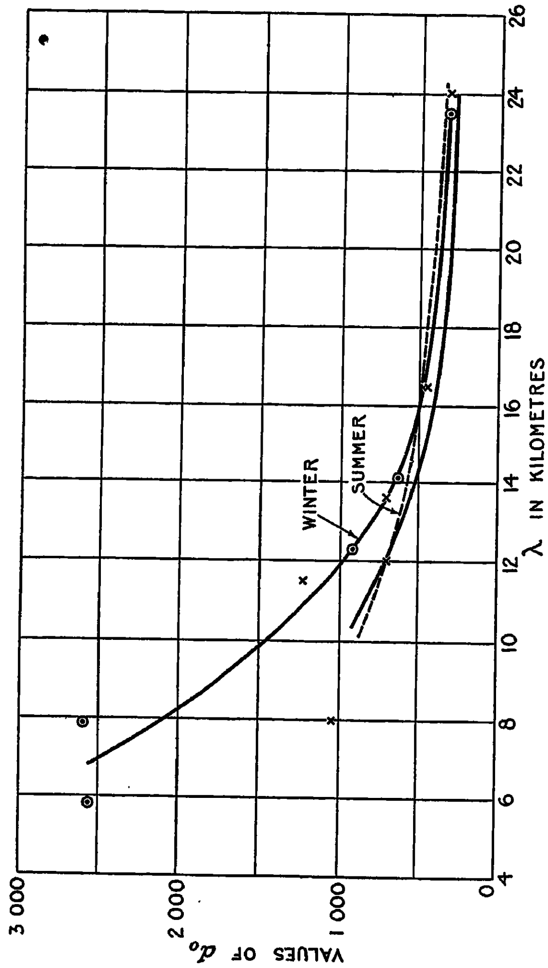

FIG. 92.

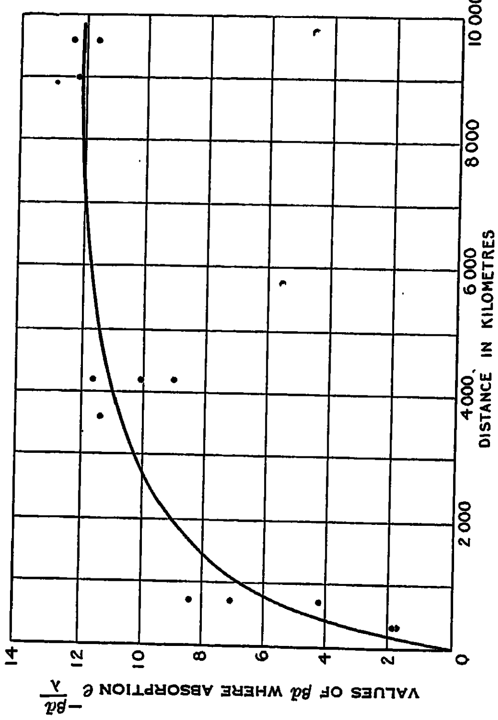

FIG. 94.

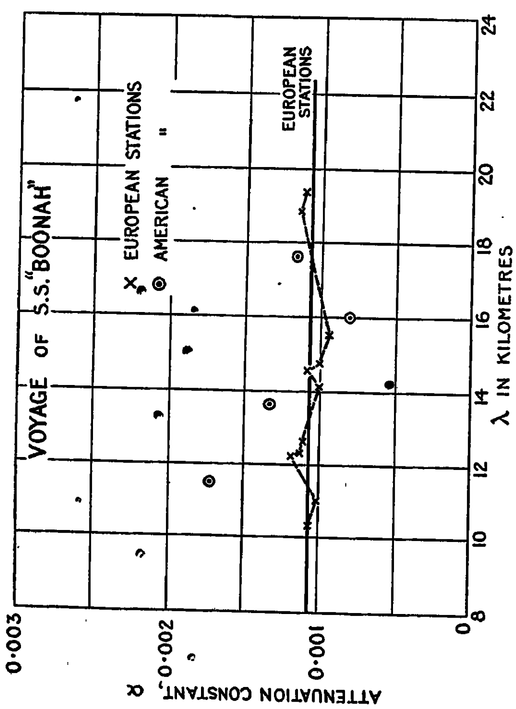

FIG. 91.

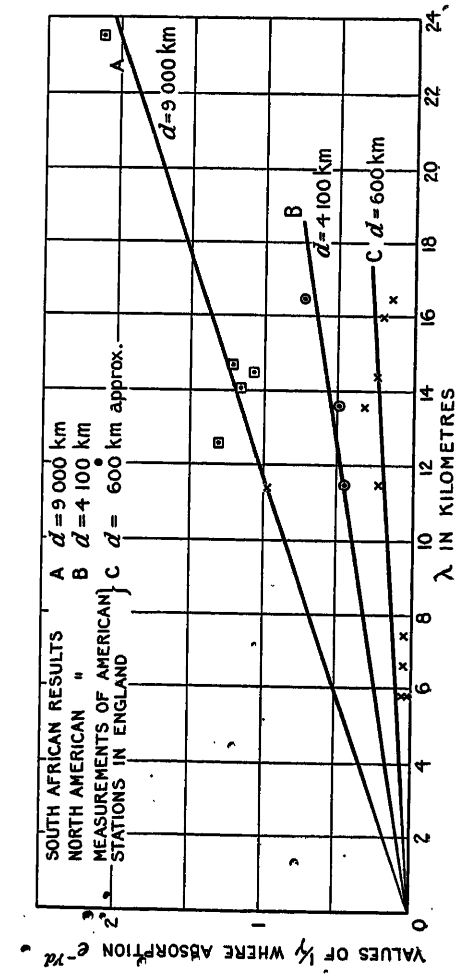

FIG. 93.

tion suffered by the signals travelling West to East during the voyage of the S.S. "Boonah" must be very considerably less than that experienced on the S.S. "Dorset" trip. The voyage of the S.S. "Dorset" took place during January, February and March, and the return voyage on the S.S. "Boonah" during June, July and August, so that the effect may be a seasonal one; but we are inclined to think this unlikely because the measured signals in Australia show no seasonal variation, and transmission of signals in the West to East direction received in Australia both from Europe and America is better than that in the opposite direction at all times. This is possibly an example of East and West effect, as it may be called, a further example of which is given in the case of the transatlantic signals, for which the attenuation constant for West to East transmission is considerably less than that found for East to West transmission.

In confirmation of this East and West effect we may cite the case of the signals from NPO, which are charted in Fig. 76. This figure shows the signals received on the S.S. "Dorset" in the Pacific, to the East of the station, and also the signals received on the S.S. "Boonah" during the return voyage, to the West of the station. It is obvious, even from a casual glance, that the latter are much more attenuated than the former, the values of the attenuation constants being 0·00190 for East to West transmission and about 0·00071 for transmission in the opposite direction.

The observations taken on the S.S. "Boonah" are complicated by land absorption, but neglecting this for the present we may determine the overall absorption coefficients between the limits of 2 000 and 10 000 km. These are given in Table 9. The instantaneous values of α, as well as the mean values of α for each station, show a remarkable constancy, and in view of the fact that the amount of land traversed by the rays varies very considerably both with the position of the transmitting station and with the ship's position, we are justified in assuming that variations in overland absorption are not very marked at distances greater than about 2 000 km. These attenuation constants are shown in Fig. 91.

The attenuation factors for signals transmitted from the American stations appear to be more variable and to increase with an increase in the frequency. The determination of the attenuation suffers very markedly from the fact that the ray direction from the S.S. "Boonah" varies rapidly with the position of the ship, and when the latter is about 14 000 km from New York the rays pass over the North and South Poles and no signals at all are received from these stations. This effect will be discussed more fully when considering long-distance transmission.

This completes the discussion on attenuation up to the relatively short distances of 10 000 km or so. The results are a little difficult to summarize, since they obviously indicate that the attenuation constant varies with the position of the ray on the earth's surface, probably even with the direction of transmission of the ray, and possibly with the season. The results obtained on the two voyages, and those obtained in South Africa and South America, are hardly sufficient to chart the world in respect of the value of the attenuation constant. We think, however, that it may be safely assumed that the transmission formula $\frac{AhIe^{-\alpha d/\lambda^{\frac{1}{2}}}}{\lambda(R\sin\theta)^{\frac{1}{2}}}$ is a fairly good approximation for over-sea transmission, and that the value of α is approximately independent of the wave-length, but depends on the locality and direction of the ray.

It was definitely proved that it was not possible to account for the observations by the effect of diffraction alone, and the Heaviside layer theory was therefore invoked. The observations are in good agreement with this theory if we assume that the nature of the layer, i.e. height, conductivity, or gradient of conductivity, varies from place to place on the earth's surface.

Absolute values of formula.—So far we have only discussed the form of the transmission formula in relation to the observed results. The absolute value depends, as we have seen, on the arbitrary distance d_0 in the expression

$$E \text{ (in volts per metre)} = \frac{120\pi Ihe^{-\alpha d/\lambda^{\frac{1}{2}}}}{\lambda(d_0 R\sin\theta)^{\frac{1}{2}}}$$

where d_0 is some function of the height and conductivity of the layer, and possibly of the wave-length. We may obtain the values of d_0 necessary to adjust the formula to give correct mean results when we know the values of transmitting current, effective height of transmitter, wave-length and d.

In the case of the observations made on the S.S. "Dorset" we have, by the courtesy of Mr. Alexanderson

of the Radio Corporation of America, the logs of the transmitting currents of the stations WQK, WGG, WII, and WSO, as well as the Pacific stations KET and KGI.

Signals from Carnarvon (MUU) were made at specified times during the outward voyage, and the transmitting currents were noted.

TABLE 10.

Values of d_0.

Station	Corrected mean transmitted current	Wave-length	Effective height	d_0
	A	km	m	km

LCM ..	260	12·3	75	910
GB ..	150	7·85	40	2 600
MFT ..	150	5·8	50	2 560

The values of d_0 given in the table are obtained in the following manner. We have

$$d_0^{\frac{1}{2}} = \frac{E(\text{obs.})(R \sin \theta e^{ad/\lambda^{\frac{1}{2}}})^{\frac{1}{2}}}{hI}$$

All the values on the right-hand side are known. d_0 is calculated for every 1 000 km and the mean value taken. The value of α is the mean of the trans-atlantic determinations. The values of d_0 are plotted as a function of λ in Fig. 92.

The values of d_0 obtained on the home voyage are complicated by land absorption, but allowing for this, in a way specified later, the results in Table 11 are obtained.

TABLE 11.

Values of d_0.

Station	Wave-length	h	I	d_0

POZ ..	12·6	140 ?	350 ?	400 ?
LCM ..	12·2	75	260	660

The values obtained all lie slightly below the previous ones, but in both cases the points lie fairly well on a smooth curve (Fig. 92).

The measurements made during 1921 in England of the signals from the American stations WGG, WII and WSO are interesting in this connection. These measurements were made before the Australian Expedition was projected, and therefore before any attenuation curves had been taken. Even then, in the absence of any experiments, we were inclined to favour, on theoretical grounds, a transmission formula of the Watson type, and the results obtained were accordingly used to determine the values of α and d_0 in the formula, assuming a constant value of d_0 for all wave-lengths between 11·5 and 16 km. The mean results obtained during the summer months were $\alpha = 0{\cdot}0016$ and $d_0 = 350$ km, and Table 12 gives the ratio of observed to calculated results.

With these values of α, d_0, and $\beta = 0{\cdot}005$ the ratios of observed to calculated values are given in Table 12.

β = land absorption coefficient (see later).

Test No. 1 at Broomfield, near Chelmsford, May 5 to 24, 1921.
Test No. 2 at Broomfield and Girvan, July 5 to 10.
Test No. 3 at Broomfield and Towyn, Aug. 31 to Sept. 9.
Test No. 4 at Broomfield and Poldhu, Oct. 10 to 19.

These results refer to the ratio of the mean observed result to the mean calculated result throughout each test. (Day values alone are included.) In view of the later confirmation of these values on the expedition of the S.S. "Dorset," the results are remarkable. The assumption of a constant value of d_0 is inclined to increase the apparent value of α, so that the summer value of α may be either equal to or less than the winter values.

In the light of the measurements made on the S.S. "Dorset" and S.S. "Boonah," which show that d_0 varies approximately as $1/\lambda$, the American summer

results, obtained at Girvan and Poldhu, where they are not complicated by land absorption, have been re-analysed on the assumption that $d_0 \propto 1/\lambda$, and the oversea absorption has been obtained. The results of these deductions are $\alpha = 0\cdot00138$ and $d_0 = 9\,400/\lambda$ approximately, in which case the ratio of observed to calculated signal strength is given in Table 13.

TABLE 13.

Ratio of observed/calculated.

Station	Wave-length	Girvan	Poldhu
	km		
Marion	11·5	0·764	0·878
New Brunswick ..	13·6	1·025	1·160
Tuckerton	16·15	1·973	1·004
Rocky Point	16·45	—	1·000
Mean =		0·921	1·01

The agreement is rather better than on the previous theory, and the value of α, i.e. 0·00138 for summer transmission, is slightly less than that for winter transmission, $\alpha = 0\cdot00144$.

These measurements on the American stations were continued practically throughout the year and it was discovered that there was a very marked annual variation, which is shown in Fig. 14. At the end of October or beginning of November there is a very marked drop of signal strength, which persists practically throughout the winter. This drop in signal strength in the winter months may be due either to a slight increase in the attenuation in these months or to an increase in d_0, or it may be due to both. In view of the evidence that the value of d_0 is greater in winter than in summer (see Fig. 92) this latter effect is certainly present, but the magnitude of the change is not sufficient to account for the whole difference between the winter and summer results. We think, therefore, that there is some slight change in attenuation as well.

LAND ABSORPTION.

The separation of the land absorption from the atmospheric absorption is a matter of considerable difficulty. If the value of the over-sea or atmospheric attenuation had been sufficiently constant, i.e. the same for all points on the surface of the earth for all directions of the ray, etc., it would have been a matter of little difficulty to calculate what the signal strength should be if there were no land absorption, and compare it with the actual result and attribute the difference to overland absorption. For in general where the ray passes over a considerable amount of land the signal strength is weaker than that calculated on the assumption that "atmospheric absorption" alone is present. The difference is due to the energy lost in transit over the land. Since, however, the atmospheric absorption varies from place to place, it is difficult to know when comparing transmission over sea with that over land how much of the difference to attribute to over-land absorption and how much to local differences of atmospheric absorption.

The comparison therefore entails a certain amount of guesswork in fixing the probable amount of atmospheric absorption, and the determination of the land absorption is open to a certain amount of doubt. A general survey of all the results obtained up to date will help to point out the main effects of the presence of land. In the first place, measurements in South Africa show that, metre-ampere for metre-ampere, the signal strengths of the European stations are about 50 per cent of the signal strengths of the American stations. The rays from the European stations are practically wholly over land, whereas transmission between New York and South Africa is practically wholly over sea.

The difference is probably not entirely due to over-land absorption, for the direction of the New York–South African great circle is slightly more favourable for transmission than the Europe–South Africa great circle. The latter is practically due South and the former is at least partly from W to E, a direction which we have found favours transmission. Assuming, however, that the atmospheric absorption is the same in both cases, we get what is probably a slight over-estimate of the over-land absorption for the Europe–South Africa route.

The average overall attenuation constant for the American stations WQL, WQK, WII, and WSO on the transmission route to South Africa is 0·00113, and is very well determined. Using this value of α for the European stations we get the values of the ratio of observed to calculated signals shown in Table 14.

TABLE 14.

Station	Ratio	$\beta d/\lambda$	d(land)
			km
Hanover (OUI) ..	0·450	0·800	9 100
St. Assise (UFT) ..	0·430	0·845	9 000
Carnarvon (MUU) ..	0·436	0·830	9 600
Nauen (POZ) ..	0·508	0·677	9 100

The atmospheric absorption of Bordeaux (LY) on a 23·45 km wave being abnormally high, it is not included, but the signals are abnormally low, suggesting as before a large atmospheric absorption.

If we assume that the land attenuation is of the form $e^{-\beta d/\lambda}$ the values of β are:

	β
Hanover	0·00129
St. Assise	0·00136
Carnarvon	0·00121
Nauen	0·00129
Mean	0·00129

It will be noted that β is fairly constant.

SHORT-DISTANCE LAND ABSORPTION.

Another set of fairly unequivocal determinations of the land absorption can be obtained from measurements of the American stations in England during 1921. A

fairly accurate estimate of the atmospheric absorption has been made in transatlantic transmission. If allowance is made for this in comparing the simultaneous results obtained at Girvan and Chelmsford, the absorption of the ray when travelling over the 600 km of land included in the path from New York to Chelmsford can be calculated.

The curves shown in Fig. 93 are compiled from the data just cited. The value of $1/\gamma$ is plotted against λ, where the absorption factor is assumed to be of the form $e^{-\gamma d}$. This method is adopted since preliminary measurements suggest that $\gamma \propto 1/\lambda$ nearly, or $1/\gamma \propto \lambda$. The results at first sight appear to be meagre, but it must be remembered that, in general, each point represents a large number of observations.

It is fairly obvious from Fig. 93 that γ is a function of d, the distance travelled over land, as well as of λ, the wave-length. It will be observed that at distances greater than about 3 000 km γd is constant; this is shown in the curves of γd plotted against distance (Fig. 94). For small values of d, γd is proportional to d, but as d increases the quantity γd tends to a limit. The practical significance of this is very remarkable and is of considerable importance. Since the ratio of the actual signal strength for the over-land path to the strength which would be obtained if the path were over sea, is $e^{-\gamma d}$, the results show that the effect of land absorption tends to a limit after a distance of about 3 000 km is reached. Thus, however far the ray travels over land, beyond a distance of 3 000 km the effect of the land is only to produce a limited reduction in strength, which is about 50 per cent for wave-lengths in the neighbourhood of 15 km. The range of wave-lengths to which this law applies with any certainty is, say, 10 to 25 km.

The material is hardly sufficient to determine the exact law of variation of γ with wave-length, the range of wave-lengths being too small, but it may be conjectured that $1/\gamma$ increases with λ, possibly at some rate between the first and second power, since the observations on short wave-lengths suggest that the increase is more than linear. It seems unlikely at any rate that $1/\gamma$ varies as $\lambda^{\frac{1}{2}}$, as is the case with atmospheric absorption, so that the mechanism of over-land absorption is probably quite different.

THEORY.

Any theory which will account for all these effects is necessarily very complex, the nature of the absorption being different for long-distance and short-distance over-land transmission, as well as for long wave-lengths and short wave-lengths.

The waves in passing over the earth's surface produce currents in the earth and, on account of the resistivity of the earth's material, power must be supplied, which will result in attenuation of the signal. Other losses that may be present at the earth's surface, and which will cause absorption, are:

(1) Dielectric loss in the surface vegetation, and
(2) Conduction losses in the various structures on the surface, as well as the surface vegetation.

With regard to (1), experiments on the resistance of aerials have shown it to be present to quite an appreciable extent. The presence of trees, iron-frame buildings, etc., will no doubt produce a certain amount of loss. It is probable that all these factors are present in any actual case. The evidence, however, points to the fact that the conduction loss in the earth is negligible compared with the others at, say, more than a few hundred kilometres from the transmitter.

At these distances we can picture the wave as being approximately uniformly distributed in the space between the earth's surface and the upper conducting layer, and the nature of the transmission, as has been shown before, is practically the same as that between two conducting planes. The total attenuation can then be shown to be the sum of the attenuations due to the upper conductor and the lower one separately, being, in fact,

$$\frac{1}{2H}\left\{\left(\frac{\rho_1\mu_1}{2c\lambda}\right)^{\frac{1}{2}} + \left(\frac{\rho_2\mu_2}{2c\lambda}\right)^{\frac{1}{2}}\right\}$$

that is

$$\frac{\mu^{\frac{1}{2}}}{2H(2c\lambda)^{\frac{1}{2}}}\{\rho_1^{\frac{1}{2}} + \rho_2^{\frac{1}{2}}\}$$

where H = distance between the upper and lower conductors,
λ = wave-length,
ρ_1, ρ_2 = resistivities of the upper and lower conducting layers respectively, and
c = velocity of light.

The value of ρ_2, the resistivity of the earth, varies, of course, enormously from place to place, but measurements made in various parts of England show that as a rule it varies between 10^{12} and 10^{13} C.G.S. units.

The amount of contribution of the earth currents to the total attenuation, i.e. $(\mu_2\rho_2)^{\frac{1}{2}}/2H(2c\lambda)^{\frac{1}{2}}$, depends on the distance H between the earth's surface and the upper conducting layer, but we can easily put a lower limit to H from the known constants of the atmosphere, and a value of H = 10 km will be well below the least possible height of the layer.

Inserting these values in the above quantity, we find that anywhere within the wave-length range 6 000 to 24 000 m the attenuation due to this cause is absolutely negligible. In any case the actual attenuation varies as $1/\lambda^n$ where $n > 1$, and the attenuation due to earth currents varies as $1/\lambda^{\frac{1}{2}}$, so that in view of these two reasons this source of attenuation is probably negligible except, possibly, close to the transmitter.

SURFACE DIELECTRIC LOSS.

The attenuation caused by this surface loss can be shown to vary approximately as $1/\lambda$, as is required by the observed results; for consider the space between two surfaces S_1, S_2 (Fig. 95), perpendicular to the direction of propagation of the wave and to the bounding surfaces, and let us suppose as a first approximation that the electric force is uniformly distributed between the upper layer and the earth.

Then, by Poynting's theorem, the rate of supply of energy through the surface S_1 per unit depth is $\frac{c}{4\pi}(XHM)$

where X = electric force, and
M = magnetic force,

and, since $M = cX$,

$$P_1 = \frac{c^2H^2(X)^2}{4\pi}$$

and the power supplied through S_2 is

$$P_2 = \frac{c^2H^2(X_1)^2}{4\pi}$$

The difference in the powers supplied through the two surfaces is equal to the power wasted in dielectric

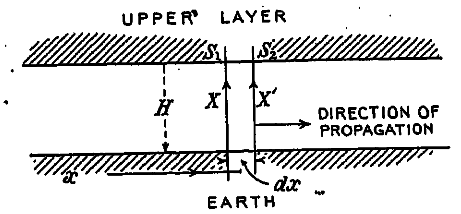

FIG. 95.—Showing land absorption.

loss, i.e. gnX^2dx, where g is a constant, n is the frequency and dx is the distance between the two surfaces. Thus

$$\frac{c^2}{4\pi}H(X^2 - X_1^2) = gnX^2dx$$

and

$$X_1^2 = X^2 - \frac{\partial X^2}{\partial x}dx$$

so that

$$-\frac{cH^2}{4\pi}\cdot\frac{\partial X^2}{\partial x} = gnX^2$$

or

$$X = X_0e^{-gn4\pi x/(2c^2H)}$$

The absorption coefficient is then

$$\frac{4\pi gn}{2c^2H} = \frac{2\pi g}{cH\lambda}$$

which, it will be observed, is inversely proportional to λ. It is also inversely proportional to H, as in the case of the resistive loss. This latter property appears to be a natural consequence of the assumption of a surface loss.

This theory offers a rough explanation of the variation of absorption with distance. For consider the state of affairs in the neighbourhood of the transmitter. The difference in power radiated from the two spheres S_1

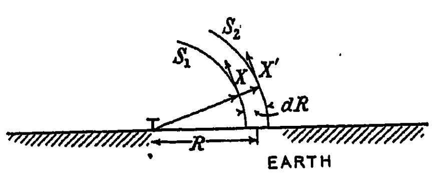

FIG. 96.

and S_2 (Fig. 96) surrounding the transmitter is approximately

$$-\frac{c^2}{4\pi}\cdot\frac{\partial X_0^2}{\partial x}\cdot 2\pi R^2\cdot\frac{2}{3}dx$$

where R is the radius of the spheres, supposed small compared with H, and the energy wasted is

$$2\pi RgnX^2dx$$

that is,

$$-\frac{c^2}{4\pi}\cdot\frac{2}{3}\cdot\frac{\partial X^2}{\partial x} = \frac{gnX^2dx}{R}$$

or

$$X = X_0e^{-4\pi gnx/(2c^2\frac{4}{3}R)}$$

Comparing this with the previous formula, we see that H is replaced by $4R/3$, so that for values of R small compared with H the absorption on this account is large compared with the absorption at a great distance where the wave has settled down to a uniform distribution between the upper and lower layer.

This theory is admittedly only very approximate, for in the first place the distribution of the electric and magnetic fields is assumed to be unaffected by the ground loss, and, secondly, the readjustment of these forces due to the surface absorption at P, say, is assumed to take place simultaneously throughout the space between the two surfaces S_1 and S_2. This can only be approximately the case when all the distances involved are small compared with λ. Nevertheless, further analysis confirms the main conclusions, viz. that on account of the surface loss the absorption factor decreases with the distance.

A more accurate method of attacking this problem is to consider the ray passing from transmitter to re-

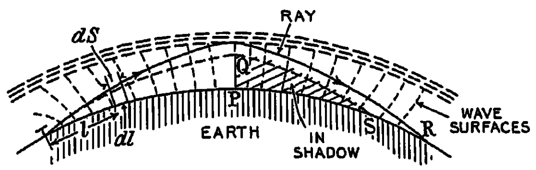

FIG. 97.

ceiver. Although as yet we have very little information as to the path of this ray, there can be little doubt that when transmission takes place over a long distance the ray passes at a considerable height over the earth's surface. Thus we can picture it as being somewhat of the form shown in Fig. 97.

The reflection at the upper surface is supposed to be continuous and gradual, more resembling refraction than reflection pure and simple. The wave surfaces, instead of being, as before assumed, perpendicular to the earth's surface are perpendicular to the ray and are slightly tilted, the state being only slightly different from that assumed previously.

Considering the ray from the point of view of pure optics, we know that if a screen is placed at PQ, say, the top edge of which is below the ray, and if the height of the ray above the surface of the earth is more than a few wave-lengths, then the screen will not impede the ray and the reception of energy at R will be practically unaltered. The region below QS will be in electrical shadow, to an extent depending on the dimensions of the screen PQ compared with the wave-length. When the screen is big enough there will be practically no electromagnetic forces at the earth's surface in the region beyond P. Consequently there can be no losses in the ground in this region; but since the screen makes practically no difference to the signal received, the contribution by ground loss to the attenuation

in the region beyond P must be negligible if the ray passes at a sufficient height. The validity of this argument rests on the assumption that the height of the ray should be more than a few wave-lengths above the surface, so that the region QS is in the shadow. To answer the question "How many wave-lengths?" requires a rather detailed mathematical discussion, the outlines of which are given here.

The energy loss is a local effect at the surface of the earth, and the effect of this energy loss on a ray at a given height can be calculated when the surface distribution of electric forces and currents is known. The total effect of this can be obtained by summing up the effects of these at a point P on the ray, due attention being paid to the fact that it takes a definite time, i.e. r/c, for the currents on the earth's surface to produce their effects at P, so that the distribution in time as well as in space must be known (see Fig. 98).

If the wave travels in a medium above the surface of the earth with the velocity of light, the time taken for a change at Q to produce its effect at P is r/c, where r is the distance from Q to P, and c is the velocity of light.

The fact, however, that the ray bends round with the curvature of the earth, as in Fig. 97, shows that the actual "phase velocity" of the wave increases with the height and so the actual time taken by the wave along the path is less than that taken along the

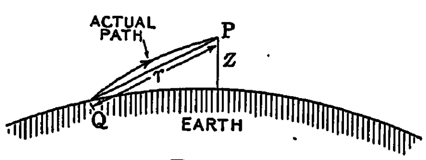

FIG. 98.

direct path QP (by Fermat's principle), which in its turn is also less than the time taken along QP in the free ether. It follows, therefore, that $T < r/c = kr/c$, say, where k is a quantity less than unity. If we assume that the distribution of current on the earth's surface is sinusoidal, the wave-length being practically the same as that in free space, we have sufficient data to calculate the disturbing effect of the surface loss on the ray at P, say, a height Z above the earth's surface.

Making these assumptions the following theoretical results were obtained, k being assumed to be 0·99, i.e. differing only by 1 per cent from unity. In Fig. 99 is shown the relative effect of land absorption on a ray at different heights. The ordinates represent the absorption on an arbitrary scale and the abscissæ the heights. The wave-length assumed is 20 km.

If k is a constant for all wave-lengths, then the ordinates are only a function of Z/λ, Z being a height above the earth's surface, so that the same curve applies for different wave-lengths if the horizontal scale is altered in proportion to λ. The curve obtained is very approximately exponential, so that the absorption for rays of different heights is expressible in the form $e^{-mZ/\lambda}$, where m in the case assumed is 1·06, Z and λ being in km with a wave-length of 15 km. The absorption at a height of 50 km is therefore $e^{-1\cdot 06 \times 50/15} = e^{-3\cdot 53} = 0\cdot 029$, say 0·03 of its surface value, i.e. is practically negligible.

On the assumption that the absorption decreases exponentially with the height, we can get an estimate of the relation between the total absorption and the distance between receiver and transmitter. The actual total absorption will be the sum of the absorption per unit length, i.e. $\int \beta_z dZ$, where β_z is the value of the absorption factor at height Z. Now $\beta_z = \beta_0 e^{-\gamma_1 Z}$, say, where β_0 is the value of the absorption when the ray is close to the surface, and Z is the height of the ray above the ground. Now ds, the element of length measured along the ray, is practically indistinguishable from dl, where dl is the projection of ds on the earth's surface (Fig. 98), so that the total absorption is approximately

$$X = \int \beta_0 e^{-\gamma z} dl$$

In order to make this determinate we must express Z as a function of l. On the simple assumption that the height Z of the ray is proportional to the distance travelled we get

$$X = 2\int_0^{d/2} \beta_0 e^{-\gamma (Z/d) l} dl$$

$$= 2\int_0^{d/2} e^{-\gamma P l} dl$$

where Z/l constant $= P$ say.

$$= \frac{2\beta_0}{\gamma P}(1 - e^{\gamma P d/2})$$

$$= \frac{\beta_0}{S}(1 - e^{-sd})$$

where $S = \gamma P/2$.

When sd is sufficiently small this is $\lambda = \beta_0 d$; but the total absorption X tends to the limit β_0/S as d increases. With regard to these two characteristics, this theoretical value agrees with the actual values, for the curve (Fig. 94) is very approximately of the form $A(1 - e^{-sd})$. The coefficient A in the actual curve is, however, not β_0/S but is approximately $2\beta_0/S$, so that the simple assumption that the height of the ray is proportional to the distance is not justified. The agreement is such, however, as to confirm the belief that the explanation given is approximately correct.

Summarizing the above, apart from theory, when we wish to take practical account of the effect of land absorption and calculate the reduction in signals effected by it we must proceed as follows: In the first place, where there is an unbroken stretch of land between the transmitter and receiver, these being a distance d apart, ascertain from the curve the value of βd corresponding to this distance, and divide this by λ, the transmitting wave-length. If the resulting quantity is x, then the effect of the land absorption is to reduce the signals in the ratio of e^{-x} to 1, roughly.*

This procedure obviously takes no account of variations in land absorption and can therefore be considered to be only a sort of average effect, but it apparently

* The values of the European station E.M.F. observed on the S.S. "Boonah" have been corrected with this factor in determining the values of d_0.

serves to give results with a fair degree of accuracy for wave-lengths ranging between 5 km and 25 km.

When the land does not stretch continuously between the transmitter the procedure is more complex, but working on the principle that land is only effective in the neighbourhood of the transmitter or receiver it is not difficult to get an estimate, by using Fig. 94, of the effect in any given case.

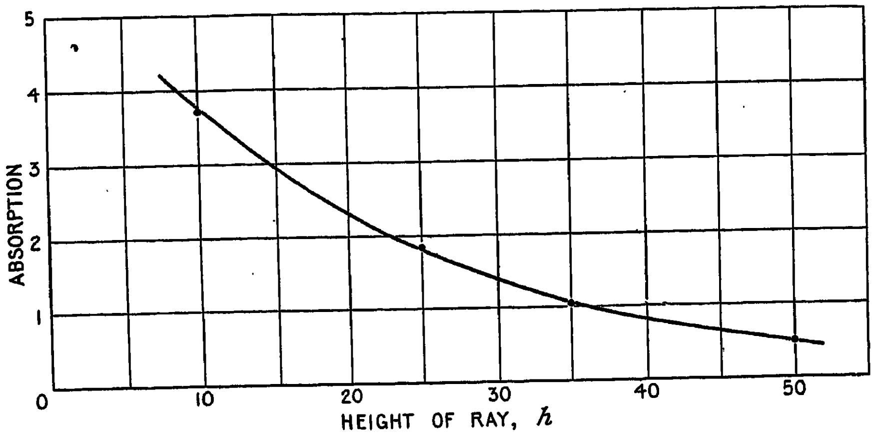

Fig. 99.

The effect of land absorption due to land close to the receiving station is shown clearly in Fig. 67, where the increase of signal strength on clearing the Indian peninsula is particularly marked.

Night Attenuation.

At great distances (when the short path is in daylight the longer path is practically wholly in darkness) the signals come round both ways and interfère. Signals may prefer to come round by the long path (the attenuation being less at night) even when this path is as much as two-thirds earth's circumference and the short path only one-third. The American signals are an example of this, for beats due to the bi-directional signals began to appear at a distance of only about 13 000 km West of New York.

In order to study these long-distance effects quantitatively we require a knowledge of the night attenuation. Unfortunately, only few night readings were taken, either on the voyage out or on the return voyage, since it was impossible to keep a 24-hour watch, but this want can be made good by some observations published by Lt. M. Guirre in *Radioélectricité*, March and May, 1921. The observations were taken on the French battleship " Aldebaran " during a voyage through the Mediterranean and the Suez Canal, and down the coast of Africa to the Island of Réunion.

The transmitting station was Nantes using two different wave-lengths—9 000 and 11 000 m. Although the method of measurement does not give the absolute values of the signal strength, the relative values are correct, and this is sufficient to determine the form of the attenuation curve and thereby the attenuation.

A sufficient number of night readings were taken to give a fairly well-determined average curve. A transmission formula of the type already found for day transmission fits the curve fairly well. The attenuation constant, as of course would be expected, is very much less than that found for day signals. Its value is 0·00068. This value is in good agreement with that determined for night transmission to Australia (Melbourne) and we may use it provisionally to determine the average values of night signals; by " average " is meant not only the average of a single night but of a period of, say, at least a month.

With this as a provisional basis we may go on to discuss long-distance transmission.

Bi-Directional Transmission.

The characteristics of long-distance transmission can be best explained as follows: the shadow line and the signal ray are both great circles on the earth's surface; therefore, half the ray path is always in darkness and half always in light. The transmission characteristics, however, depend on the relative positions of transmitter, receiver and twilight band.

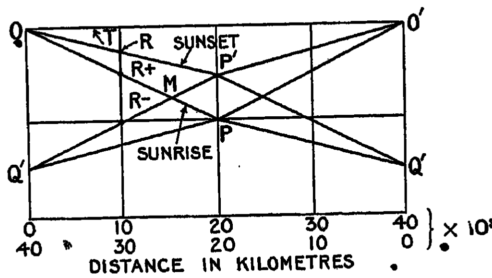

Fig. 100.

Except in the unique case where the receiver and transmitter are antipodal (i.e. at opposite ends of a diameter) there are three possible conditions, which can be illustrated by Fig. 101. Let PQRS be the signal great circle, T and R being the transmitter and receiver respectively, and let PMON be the shadow band. Then the shadow band may either cut the short segment TR once or not at all. In the latter case T and R

are either both in the light or both in the dark, so that the three conditions are:

(1) T and R both in light.
(2) T and R both in dark.
(3) One in light and one in dark.

ATTENUATION.

Under the conditions (1) and (2) the transmission, which is primarily dependent on the amount of light and darkness on the two paths, will remain constant for quite a considerable period of time, except when T and R are nearly 180° apart.

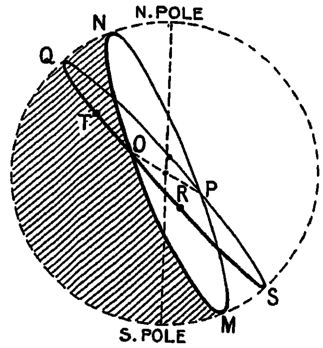

FIG. 101.

Under condition (3), however, the transmitted signals will rapidly alter, since the amounts of light and darkness on the paths are changing rapidly with the position of the twilight bands. The two more or less stable states occur, therefore, under conditions (1) and (2).

An examination of Fig. 101 will show that these states occur between sunrise at the receiver and sunset at the transmitter, and between sunset at the receiver

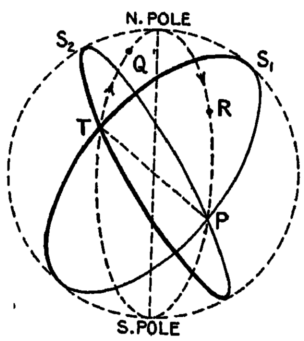

FIG. 102.

and sunrise at the transmitter, if R is less than 180° West of T, and vice versa if R > 180° West of T.

Under these conditions it is possible to state the total attenuation on the two paths without having to specify the exact time, and the comparison between observed and computed signal strength will, in general, be made at these stated times. It is the more natural to do this because the signals (*a*) are usually at their maximum at these times, and (*b*) are not complicated by the effect of crossing the shadow band, the effect of which is always difficult to allow for. We may therefore proceed to calculate the total attenuation under these two conditions.

The total attenuation (for a given wave-length), i.e. $\alpha d/\lambda^{\frac{1}{2}}$, can be plotted against distance, both for the daylight and night paths; the curves obtained will, of course, be straight lines. These are represented in Fig. 100.

For any given point on the globe there are two great circle distances to the transmitter, one less than 20 000 km and the other greater than 20 000 km, the sum of the lengths being, of course, 40 000 km. This is represented in Fig. 100 by the scales originating at the extreme left and extreme right respectively.

In the stable state, the short path (1) is wholly in light and the attenuation is represented by the ordinates

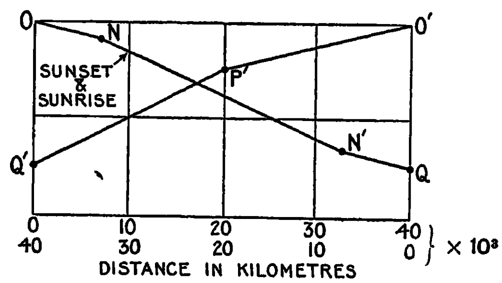

FIG. 103.

to OPQ, i.e. SR, and in Fig. 100 the slope of the line OP is α_1.

The long path is partly in darkness and partly in light, and the total attenuation, i.e. $\alpha_2(20\,000)/\lambda^{\frac{1}{2}} + \alpha_1(20\,000 - d)/\lambda^{\frac{1}{2}}$ is represented by the ordinate to the broken line O′PQ′, i.e. SR. Again, by the same reasoning, under condition (2) the absorption on the two paths will be represented by the ordinates to the lines OP′Q and O′P′Q′ respectively.

It will be observed that the signals by the two paths

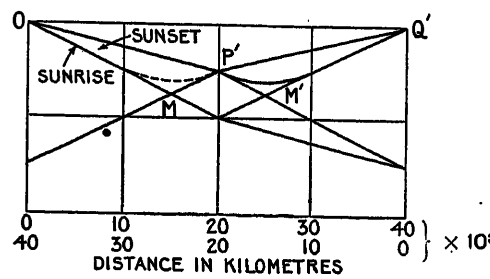

FIG. 104.

are equal at M and N with the values of α_1, and α_2 obtained by observations for relatively short-distance transmission is about 15 000 km from T by the shorter all-day path. At any point further than this the signals will prefer to come by the longer path, for they are on the whole less attenuated, since 20 000 km of this path is in darkness. At smaller distances than 15 000 km the signals by the short path are strongest.

An exceptional case occurs when the ray TR lies between TS_1 and TS_2, where TS_1 and TS_2 are the great circles of the shadow band at sunrise and sunset respec-

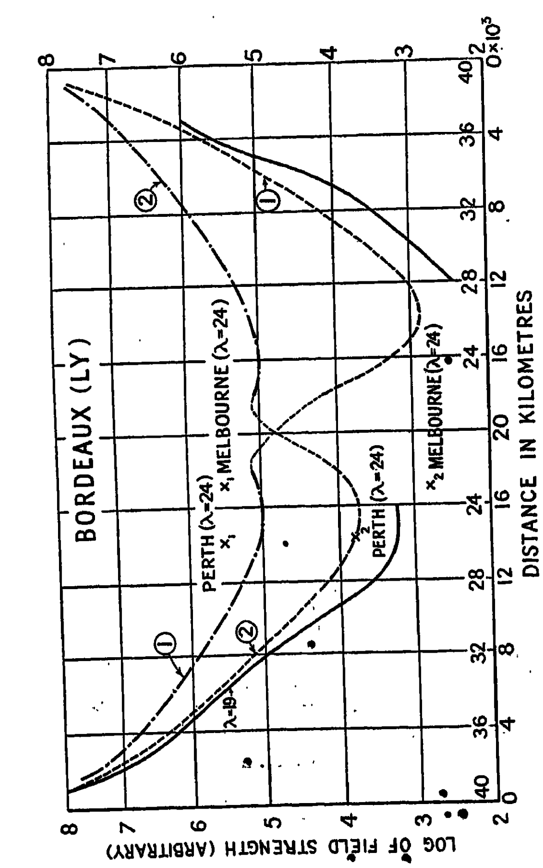

FIG. 105.

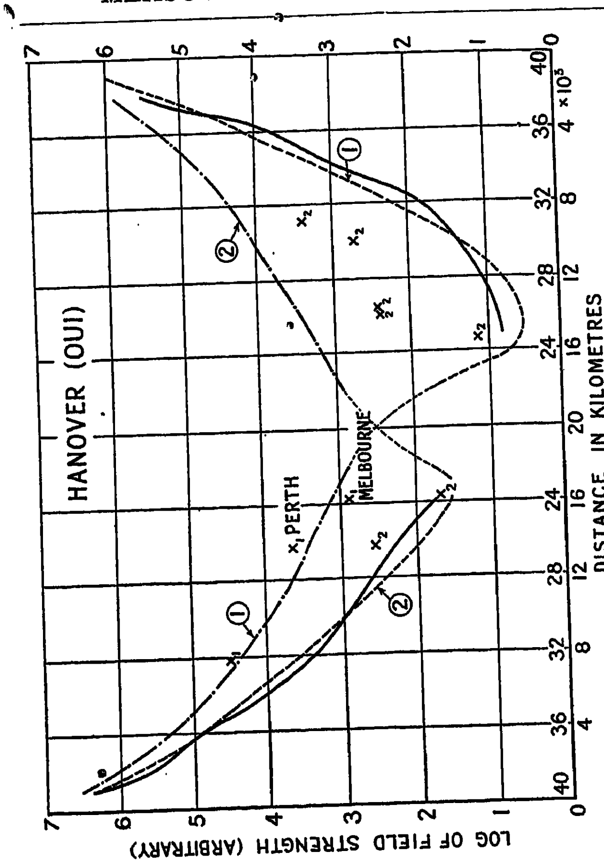

FIG. 106.

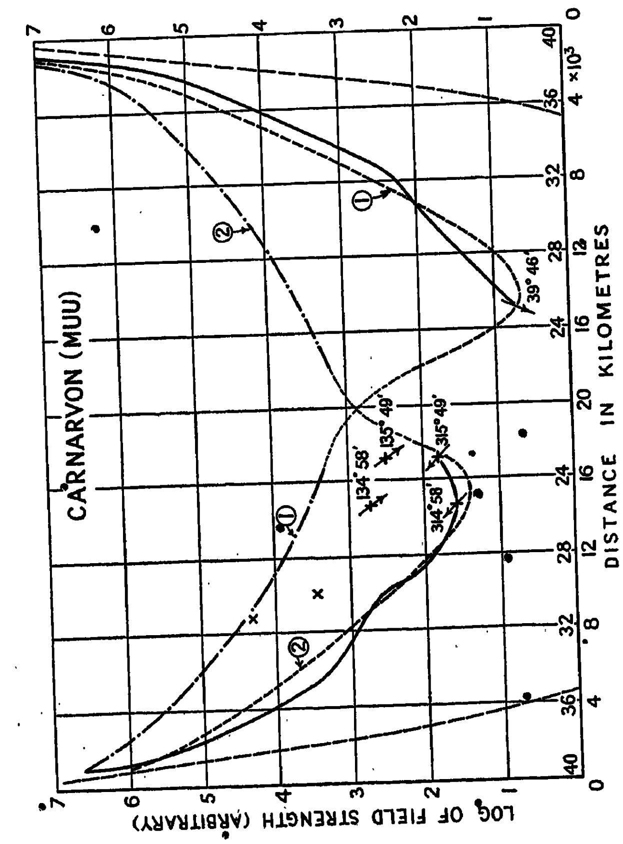

FIG. 107.

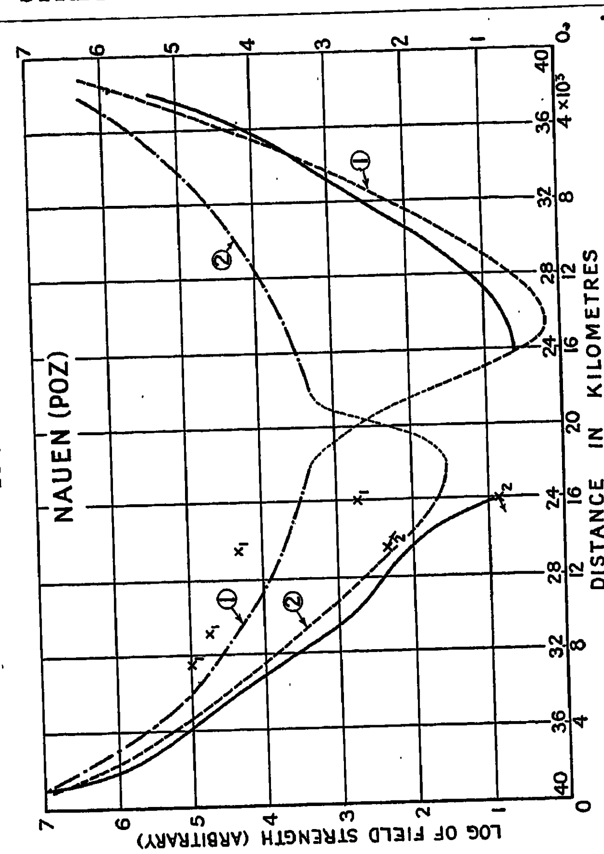

FIG. 108.

tively, so long as R lies on the short path beyond Q, where Q is on the same latitude as S_1 and S_2 (see Fig. 102). The shadow band cuts the arc TR whenever T is in darkness, so that the maximum* arc for which T and R are both in darkness is TQ and the corresponding absorption curve is ONN′Q (Fig. 103).

Apart from this exceptional case the two sets of curves OPQ, OP′Q, O′PQ′ and O′P′Q′ represent the absorption for West to East and East to West respectively for the occasions when the shorter arc between the receiver and transmitter is wholly in light or wholly in darkness.

The actual signal strength at M where the signals from the two directions are approximately equal will depend on the relative phase of the two sets of signals, and if this relative phase alters the apparent strength will alter. Since the actual paths of the rays pass through the upper atmosphere, where the effective electrical length of the paths may reasonably be expected to alter fairly rapidly, the relative phase of the two sets of signals will also alter and rapid pulsations of signal strength will occur. These fluctuations have actually been observed, originally by Messrs. Beverage and Rust at Rio, the signals being those from the American station Cavite, and almost simultaneously by Tremellen on the S.S. "Dorset" when it was in the Pacific about 13 000 km from the American stations, from which the effect was most marked.

It was possible to show that the signals came round the world in the two opposite directions by using a unidirectional receiver and receiving first one and then the other set of signals. With this receiver no fluctuations or beats were observed, since only one set of signals was received at a time and the interference between the two sets was avoided.

Returning to Fig. 100, it will be noted that the actual signals received under condition (1), for instance, are obtained from a combination of the curves OPQ and O′P′Q′, and in Fig. 104 the composite curves OMPO′ and OPM′Q′ have been drawn, which represent the sum of the signals from both directions.

In the region of M and M′ the strength is variable on account of fluctuations, but the actual curve represents the maximum value which occurs when the signals from the two directions are in phase; also along the branches MO′ and OM′ the signals are variable on account of the fluctuations which occur at night. To get the final curves, log $1/(R \sin \theta)^{\frac{1}{2}}$ is added to the ordinates of the previous curves, where R = radius of earth, and θ is the zenith angle between the two stations.

The ordinates will then, except for an additive constant, represent the theoretical values of log E, where E is the field strength in the signal, plotted against distance. The basis of this calculation is, of course, the assumption that signal E.M.F. can be represented by an expression of the form $\dfrac{AhIe^{-\alpha d/\lambda^{\frac{1}{2}}}}{\lambda(R \sin \theta)^{\frac{1}{2}}}$ (which was found to be correct for short-distance transmission), where α has the value α_1 or α_2 according as the ray is in light or in darkness. It neglects any variations which may be due to changes of α with latitude or direction of transmission of the signals. A comparison of the actual signals with the theoretical curves will then show up any deviations on account of effects.

Figs. 105 to 111 have been plotted in this manner. The plotted curves show the theoretical values calculated as above, the only alteration being that the day attenuation-constant on the West to East path is taken as 0·00107, whereas on the East to West path it is assumed to be 0·00160. The full lines represent the day mean-values, and it will be observed that only in exceptional cases do they diverge largely from the theoretical values.

The values taken on the S.S. "Dorset" in the Pacific are almost invariably greater than the calculated ones; this merely reflects the result before obtained, that the attenuation in the Pacific is less than in the Atlantic. The other divergences are due to the East and West effect at Melbourne and Perth, and are shown quite clearly on the curves for the American and long-wave stations, and Bordeaux. With regard to the American signals, the main feature is the absence of signals when the ray passes over the North and South Poles. The arrows indicate roughly the direction of signals, the vertical axis being taken as North and South.

It must be remembered that, as in the example given in Fig. 103, there is no moment during this period when the ray path is wholly in darkness, even though the length of the path is less than half the circumference. But even when the path was wholly in daylight, measurable signals should have been observed if they had been attenuated with the average value of α, and the absence of signals indicates the existence of very large values of attenuation somewhere on the path. The main features of long-distance transmission are shown up very well by this method of representation, and seem to us to leave little doubt that the assumption on which the theory is based is approximately correct.

Australian Signal Measurements.

A glance at Figs. 33 to 47 will show that the diurnal curves of the signal strength of the long-distance stations (i.e. European and American) are characterized by a double peak, the interval between the two maxima being approximately 12 hours. The peaks occur at times which are roughly those in which either the short path or the long path from the transmitter is wholly in darkness, i.e. under the conditions (1) and (2) referred to before. This is not strictly accurate, for no more than 20 000 km of the long path can ever be wholly in darkness. A more accurate statement is that the part of the path in daylight is a minimum at the other peak. Directional measurements show that the signals actually do traverse the darkened path, even though it may be considerably longer than the short daylight path.

The long-wave stations LY, at Melbourne and Perth, and WQL and WQK at Perth, are exceptions. The signals from these stations are in general practically entirely from West to East in all circumstances.

In the case of the shorter-wave stations, however, we are dealing almost entirely with night transmission.

These night or quasi-night readings differ in one respect from night readings taken at relatively short

* The cases where the transmitter or receiver is within the Arctic or Antarctic Circle are not considered, as they do not come within the range of practical working.

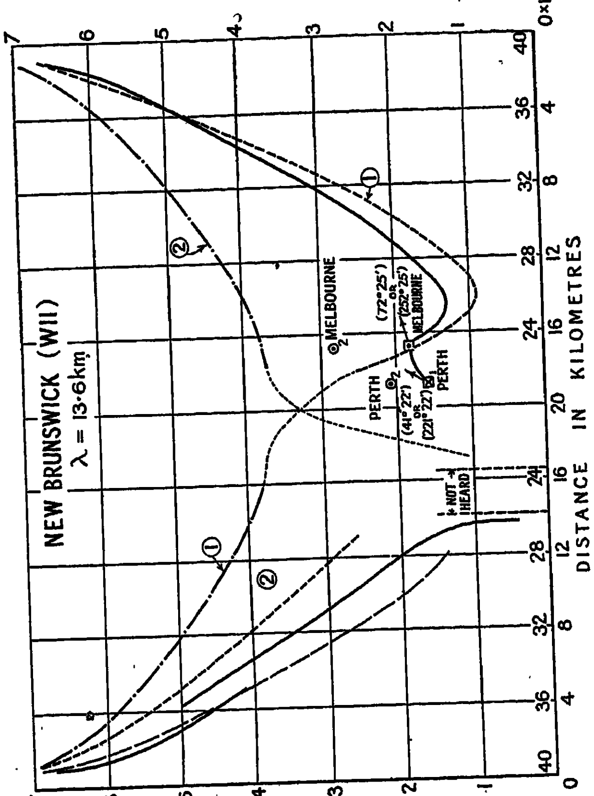

Fig. 110.

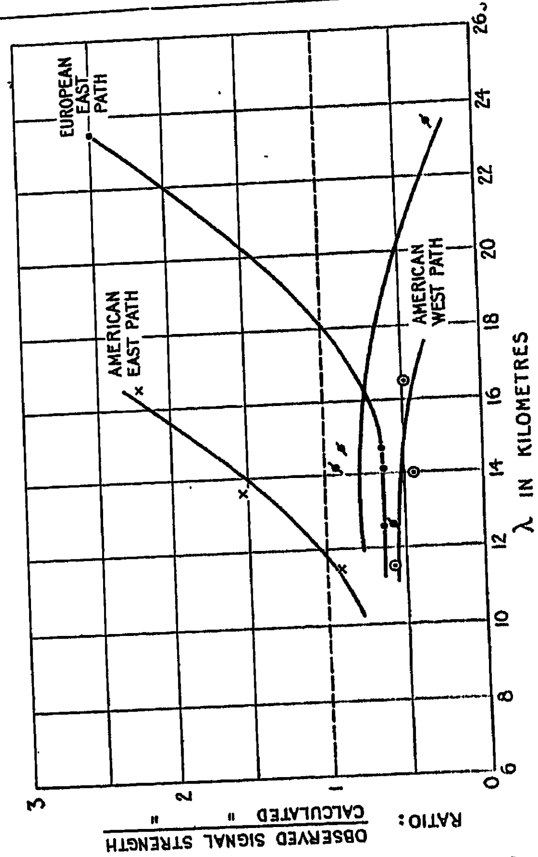

Fig. 112.

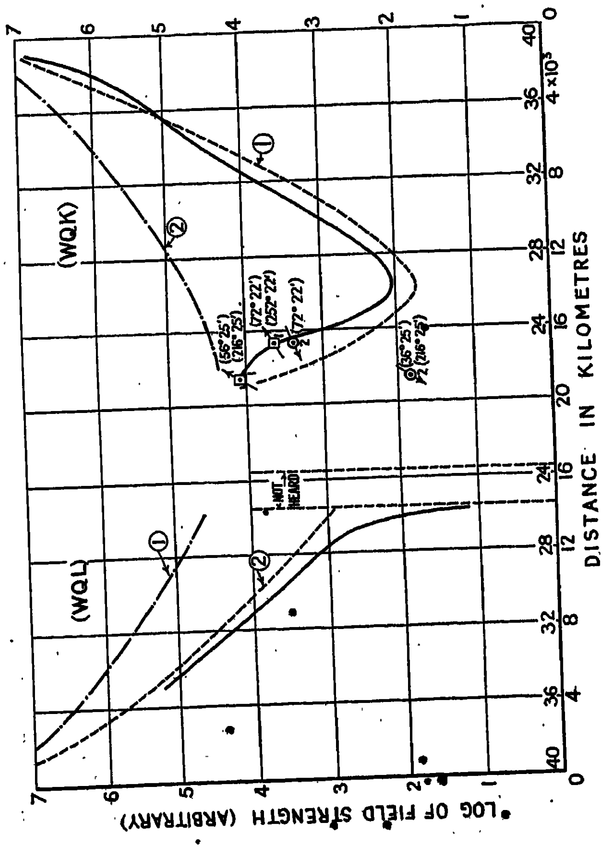

Fig. 109.

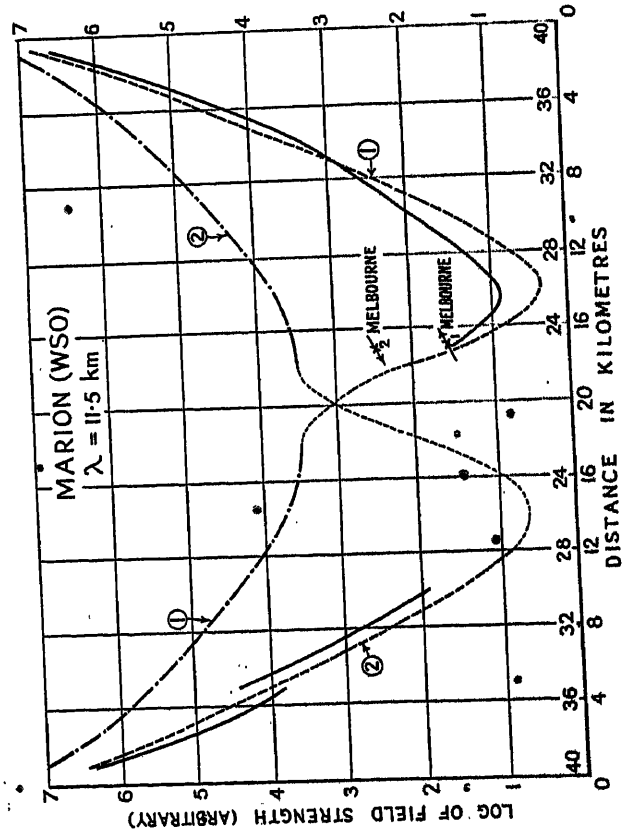

Fig. 111.

distances; they are very considerably less variable and the task of comparison with theory becomes correspondingly simpler.

We have seen that a transmission formula of the type already obtained for day transmission is also applicable in the case of night transmission. This is confirmed by the following method of setting forth the results. An examination of Table 15 brings to light the interesting fact that the maximum values of the signal strength measured at Melbourne for the shorter-wave stations are equal to the day signals (on the outward voyage) at a given shorter distance d_1, this distance being practically the same for all stations.

This means that if the day signals OUI, MUU and POZ at a certain distance d_1, which is approximately 6 500 km, are E_1, E_2, E_3, respectively, then the night signals at Koo-Wee-Rup, near Melbourne (approximately 17 000 km), of these stations are also approximately E_1, E_2, E_3. We can argue from these results that the attenuation over a distance of 6 500 km in the daytime is approximately equal to the attenuation over 17 000 km at night, except for the slight modification introduced by the different distance factors.

TABLE 15.

Table of Observations at Koo-Wee-Rup.

Station	Wave-length	E (obs.)	d_1	Actual distance to Melbourne
	km		km	km
Hanover (OUI) ..	14·7	17·1	6 000	16 290
Carnarvon (MUU) ..	14·1	12·2	6 500	17 100
Nauen (POZ) ..	18·6	18·8	6 800	16 000
American.				
Rocky Point (WQK)	16·45	30·8	9 700	16 750
Tuckerton (WGG) ..	15·9	18·75	—	16 700
New Brunswick (WII)	13·6	12·5	9 500	16 610
Marion (WSO) ..	11·5	11·25	8 800	16 940

Proceeding in this manner we get the following values for the night attenuation factor for West to East transmission of the European stations, i.e. $\alpha_N = 0{\cdot}000669$.

Again, the American stations transmitting from East to West give a value of $\alpha_N = 0{\cdot}000772$. These values, it will be seen, do not differ markedly from the attenuations derived from the night signal curve of Nantes, i.e. $\alpha_N = 0{\cdot}000677$.

It is not difficult to calculate the actual values of E when this attenuation constant is known, for we have

$$E = \frac{120\pi h I e^{-0\cdot000677 d/\lambda^{\frac{1}{2}}}}{\lambda(d_0 R \sin\theta)^{\frac{1}{2}}}$$

h, I, λ and d are known; if, therefore, we insert the known values of d_0, all the quantities on the right-hand side are known and E can be computed and compared with the observed results.

The assumption that d_0 is the same during the night as during the day is probably not justified but, in the absence of any reliable measure of the quantity, we may assume that it is. Table 16 gives the observed and calculated values of the peak values of the E.M.F. at Melbourne.

The effect of land absorption has not been included in these calculations. If we take account of this the calculated values would be rather smaller and the ratios nearer to unity. The limiting value of 50 per cent land absorption would make all the values close to unity (except, of course, in the case of Bordeaux).

These figures refer to the short-path night transmission. The calculation of the long-path E.M.F. is complicated by the fact that the signal must cross the twilight line dividing light and darkness. There is a considerable amount of evidence to show that this acts as a barrier. This is illustrated in the majority of the curves showing the diurnal variations of signal strength; also there is a very marked minimum in the half-light, half-dark period, as can be seen from all the diurnal curves. The conditions in East to West transmission are by no means regular; there is, however, a general tendency for the weakening of signals after sunset at the receiving station when the twilight band lies between the two stations.

The conditions which determine this minimum are rather complex, and are difficult to allow for. If we calculate the signal, neglecting this effect, we shall probably be inclined to over-estimate and, other things being equal, the signals would be less than the calculated values.

A glance at Tables 16 and 17 shows the unexpected result that, in the case of the long-wave station at WQK at Long Island at any rate, signals are actually considerably stronger than the calculated values by the West to East route.

These results are plotted in Fig. 112, in which the abscissæ are wave-lengths in km and the ordinates represent the ratio of observed signal strength to the calculated values. It will be seen at a glance that, in general, on the longer wave-lengths the signals going by the West to East path are in excess of what would be expected and those travelling in the opposite direction are in defect. The difference in the extreme case

of Bordeaux is as much as 5 to 1, and can therefore hardly be attributed to errors of experiment.

The fact that Bordeaux has no peak at 0600 G.M.T., and that the longer-wave American stations are at least as strong by the long route, 23 400 km, part of which is in daylight, as by the short all-night path, is a very good proof of the existence of some factor favouring West to East transmission.

It appears therefore that not only is there evidence of this effect in daytime (*vide* attenuations in the East and West directions), but there is also strong evidence of it at night, where it is specially marked on the long wave-lengths.

The results at Perth (Western Australia) are in agreement with these in this respect, but they are still further complicated by the fact that the great circles from the American stations pass through the higher latitudes.

The results of the S.S. "Boonah" expedition, it will be remembered, indicate that transmission in the neighbourhood of the North and South Poles is particularly unfavourable. On this account the signals from the American stations are weaker than would be expected in the West to East direction, and very much weaker in the opposite direction.

The case of Marion is specially remarkable. It is the farthest North of all the American stations, and therefore the bearing at Perth is to a marked extent further North and South than the other stations. The ray from this station passes nearer the Poles than any of the others. The signals from this station at Perth are consequently so weak that they were only measurable in a very few cases.

The long-wave stations WQL and WQK exhibit this East and West effect in a very marked degree, for at Perth the long path and short paths are nearly equal, the latter place being only about 1 200 km from the antipodes of the American stations, yet the signals coming by the longer West to East path are many times as strong as those coming in the opposite direction. It is hardly worth while repeating the calculations in this case, for the added complication of relatively high-latitude transmission introduces a large measure of uncertainty, since the actual values of the attenuation in these latitudes are unknown.

The observed mean peak-values have all been plotted in Figs. 109 to 111, where the differences between the actual and theoretical curves due to East and West effect and Polar transmission can be seen at a glance. The differences are rather minimized in this method by the logarithmic scale. It has not seemed worth while to analyse the diurnal curves into their Fourier components.

The semi-diurnal nature of the signal strength, as well as its connection with the times of sunrise and sunset at the end stations, is obvious enough, but perhaps the following ideal form calculated on the basis of a fixed attenuation for day transmission, and another fixed value for night transmission, may not be without interest. It reproduces in its rough feature the general form of the diurnal curves where they are not complicated by unidirectional effects (see Fig. 113).

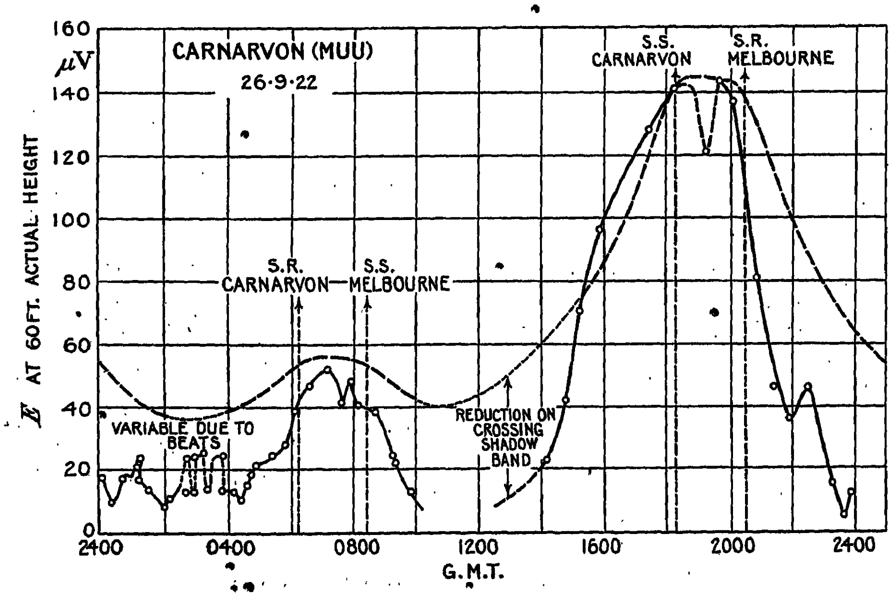

FIG 113.—At Koo-Wee-Rup. (Effective height = 12 metres.)

It will be observed that during the period in which the ray is half in light and half in darkness (i.e. 1200 and 2400 G.M.T.) the signals are actually considerably less than would be expected on the pure attenuation theory. This is no doubt only another example of the weakening of signals which occurs when they pass from day to night, and vice versa, which has already been commented upon. This effect is illustrated very clearly in Fig. 80, which shows the diurnal variation of signal strength of the European stations near the Maldive Islands.

Theoretical Conclusions.

The observations which have been analysed in the preceding sections show very clearly that the basic formula for both day and night transmission is of the Watson type, i.e.

$$\frac{AhIe^{-ad/\lambda^{\frac{1}{2}}}}{\lambda(R\sin\theta)^{\frac{1}{2}}}$$

where a is practically independent of the wave-length but may vary with latitude, local conditions, etc.

It therefore seems very probable that the assumption on which this type of formula is based, i.e. of an outer conducting layer, is approximately correct, and it is a matter of considerable interest to see whether the Heaviside layer theory can give any explanation of such facts as the difference between day and night transmission, the local variation of the attenuation constant, and seasonal effects, etc. To begin with, the theory in its original form needs modification and the assumption of a definite reflecting layer cannot be justified. For if we make such an assumption we are led into difficulties.

On the Watson theory the attenuation constant may be calculated from the resistivities of the upper and lower conducting layers and their distance apart, by means of the formula

$$a = \frac{1}{2H}\left\{\left(\frac{\rho_1\mu_1}{2c}\right)^{\frac{1}{2}} + \left(\frac{\rho_2\mu_2}{2c}\right)^{\frac{1}{2}}\right\}$$

Now we can estimate the height of the layer to be somewhere between 30 and 100 km. With any value of H between these limits we find that $\frac{1}{2H}\left(\frac{\rho_1\mu_1}{2c}\right)^{\frac{1}{2}}$ which is the contribution of the earth's or sea's resistivity to the attenuation (where $10^{11} < \rho_1 < 10^{13}$) is very small compared with the total observed attenuation coefficient.

We must therefore assume that, at any rate in over-sea transmission, practically the whole of the attenuation is due to the resistivity of the upper layer. This being the case, the observed value of attenuation, a_0 say, gives us a relation between the resistivity of the upper layer and the height of it above the surface of the earth, for

$$a_0 = \frac{1}{2H}\left(\frac{\rho_2\mu_2}{2c}\right)^{\frac{1}{2}}$$

where μ_2 is assumed to be unity and ρ_2 and H are the only two unknown quantities. If we assume the same limits for H we get limiting values for ρ_2 as well. Taking a as 0·0015 we find the limits to be $4{\cdot}9 \times 10^{13}$ and $5{\cdot}4 \times 10^{14}$ C.G.S. units.

Now it can be calculated that a well-defined layer of this resistivity acts as a nearly perfect reflector for radio waves with wave-lengths lying between 6 and 25 km, even for normal incidence.

It follows that a receiver situated, say, between 100 and 200 km from a transmitter should receive, even during the daytime, nearly as much energy by the reflected ray as by the direct ray. The reflected ray makes an angle of something like 45° with the surface of the earth. Now various observations show, without any sort of doubt, that such "high-angle reflection" is wholly absent in the daytime, and we should be inclined to put the limiting angle at about 3° or 4° at the most.

The difficulty involved here can be removed by assuming that the layer acts as a good reflector for glancing incidence, say, but as a very poor reflector for normal incidence. A layer with an ill-defined under surface will act in this way. For example, if we assume that the conductivity is zero below a certain height and has a constant gradient above this height, then the reflection coefficient (assumed small) will vary as $1/\sin^3\theta$, the gradient of conductivity, and the square of the wave-length, i.e.

$$\frac{(\sigma_1\lambda^2 c)}{8\pi\sin^3\theta(2\pi)^2}$$

where σ_1 = gradient of conductivity.

It is, of course, questionable whether a layer of this sort will attenuate the waves in just the same way as a well-defined layer. The attenuation factor will probably not be exactly of the form $ad/\lambda^{\frac{1}{2}}$ but will depend on the nature of the gradient of conductivity in the layer.

The example of a layer with uniform gradient of conductivity above a certain height may be used to show that the attenuation factor is not altered to any great extent by the assumption of an ill-defined layer.

We have found it possible to calculate the absorption suffered by a plane wave travelling between the earth and such a layer, on the assumption that both are bounded by plane surfaces, which, in the light of Watson's analysis, seems sufficiently accurate, and we have found an attenuation coefficient of the form

$$\frac{A}{H}\cdot\frac{1}{(\lambda^2\sigma_1 c)^{1/3}}$$

where σ_1 is the gradient of conductivity, A is a constant, and H = height of layer above earth's surface.

It varies as $1/\lambda^{2/3}$ instead of as $1/\lambda^{\frac{1}{2}}$, but the observations do not cover a sufficient range of wave-length to decide which is the most accurate formula. It seems probable that the formula of the Watson type is sufficiently accurate even in the case where the upper surface is ill-defined.

Height of the Upper Layer.

The measured values of the quantity d_0 in the formula

$$E = \frac{120\pi hIe^{-ad/\lambda^{\frac{1}{2}}}}{\lambda(d_0 R\sin\theta)^{\frac{1}{2}}}$$

throw some light on the "effective height" of the Heaviside layer in the daytime. A rough way of determining this is the following:

In view of the fact that high-angle reflection is absent, let us suppose that the energy radiated within a cone of angle θ (see Fig. 87) is reflected, but that higher-angle transmission than this is absorbed or, anyhow, not reflected.

The energy radiated within this cone is :

$$W = \frac{\int_0^{\theta_1} \cos^3 \theta d\theta}{\int_0^{\frac{1}{2}\pi} \cos^3 \theta d\theta} \cdot \frac{40(2\pi)^2 h^2 I^2}{\lambda^2}$$

or $$W = \frac{40(2h)^2 h^2 I^2}{\lambda^2} \times \frac{3}{8}\left(3 \sin \theta_1 + \frac{1}{3} \sin 3\theta_1\right)$$

and when θ_1 is small is

$$\frac{3}{2}\theta_1 \times 1\,600(hI/\lambda)^2 \text{ watts.}$$

If we assume, as before, that this energy is radiated through an annulus of area $2\pi R(\sin \theta)H$ (see Fig. 87), since the energy radiated per unit area is

$$\frac{1}{4\pi} \cdot \frac{E^2}{c} \text{ ergs} \quad \text{or} \quad \frac{1}{4\pi} \cdot \frac{E^2}{c} \times 10^{-7} \text{ watts}$$

$$\frac{2\pi R(\sin \theta) H E^2 \times 10^{-7}}{4\pi c} = \frac{3\theta_1 \times 1\,600 h^2 I^2}{2\lambda^2}$$

or $$E = \frac{120\pi h I}{\lambda[(\frac{1}{2}H/\theta_1) R \sin \theta]^{\frac{1}{2}}} \text{ volts/cm}$$

so that $d_0 = H/(2\theta_1)$.

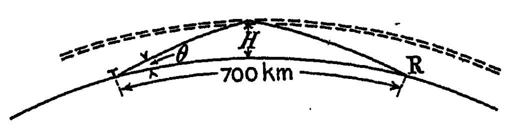

FIG. 114.

If we assume that reflection begins to be appreciable at distances > 700 km, we have another relation between H and θ. Taking $d_0 = 380$ km, we get $\theta = 3°$ and $H = 32{\cdot}1$ km (see Fig. 114). Of course the assumption of a definite limiting value of θ beyond which there is no reflection is not justified, but the method gives a value of θ which is within the limit determined by experiment, and the method may be considered to give at least a rough approximation of H.

There is another method which is based on an investigation of the propagation of waves from a radially symmetrical transmitter situated between two perfectly conducting planes, by which we can determine the equivalent height of the layer.

Thus suppose T is the transmitter situated on the lower surface; then on account of the reflection at the upper and lower conductors the electric force at R, say, is the same as that due to T, and comprises an infinite series of images spaced uniformly along an axis through T and perpendicular to the two planes, a distance $2H$ apart (see Fig. 115).

The sum of the electric and magnetic forces at R can therefore be expressed as an infinite series of terms, each term being due to one of the images. When the distance TR is large compared with H and with the wave-length, the series is so slowly convergent as to become absolutely unmanageable, but it can be transformed by a mathematical device into an integral which, in certain cases, can be simplified into quite a manageable form. A full discussion of this problem is beyond the scope of this paper, but certain results may be generalized so as to be applicable to the case under discussion.

It is generally assumed that at large distances from the transmitter the wave is approximately plane, with the electric force vertical and uniform between the conducting layers, the high-angle reflection having been cancelled out, so to speak. It can be shown that this "normal" state of affairs exists only when H is less than half a wave-length, in which case the electric and magnetic forces in the wave-front can be calculated with sufficient accuracy from the formula

$$E = \frac{120\pi h I}{\lambda[(4H^2/\lambda)r]^{\frac{1}{2}}}$$

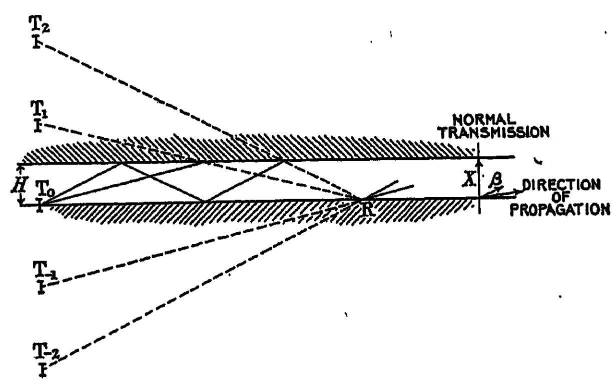

FIG. 115.

where r is the distance from the transmitter and the other quantities are the same as in the previous formulæ.

It will be observed that the electric force E varies as $1/r^{\frac{1}{2}}$, which is the appropriate factor for cylindrical transmission. When the height of the layer is greater than $\frac{1}{2}\lambda$ the state of affairs is entirely altered. High-angle reflection appears and swamps the normal wave, and when the layers are perfectly conducting the wave never settles down to the normal state but goes ricochetting from floor to roof indefinitely. This state, however, is only a consequence of the assumption of absolutely perfect conductivity in the reflecting layers. But we have seen that the actual layer is by no means perfectly reflecting, and probably has such an ill-defined undersurface that there can be no high-angle reflection. Under these circumstances even when $H > \frac{1}{2}\lambda$ the normal state of affairs obtains and the E.M.F. can be calculated from the formula

$$E = \frac{120\pi h I e^{-\alpha d/\lambda^{\frac{1}{2}}}}{\lambda[(4H^2/\lambda)r]^{\frac{1}{2}}}$$

Comparing this with the actual Watson-type formula and replacing r by $R \sin \theta$ on account of the spherical

nature of the actual reflecting surfaces, we can indentify d_0 with the quantity $4H^2/\lambda$.

Now it will be observed that, in Fig. 92, where d_0 is plotted as a function of λ the summer values of d_0 are very approximately inversely proportional to λ. The winter values decrease rather more rapidly than this. Assuming d_0 to be 400 for $\lambda = 16$, we get the value of H thus

$$\frac{4H^2}{16} = 400\,; \quad H^2 = 1\,600\,; \quad H = 40\,;$$

which is in fairly good agreement with the approximate value previously obtained.

The winter values of d_0 are rather higher than the summer values, suggesting a greater value of H_0. Summarizing, we may fairly safely conclude that in the daytime there exists a conducting layer at a height somewhere between 30 and 40 km. This layer has a very ill-defined under-surface and acts as a good reflector for a glancing incidence but as a very bad reflector for large angles of incidence. The height of the layer is probably greater in winter than in summer.

It is interesting to note how well this purely radio evidence agrees with the evidence derived from other sources, i.e. the study of terrestrial magnetism. Briefly, S. Chapman, who has worked out the subject very thoroughly on the basis of terrestrial magnetism, has concluded from the evidence afforded by the diurnal and lunar magnetic variations that there exist two conducting layers: (*a*) the permanent auroral layer, extending over a height of approximately 80 km to 300 km, and (*b*) a lower layer present only in the daytime. The latter is probably due to the ionizing effects of the sun's γ radiation. Its height will naturally depend on the zenith distance of the sun, i.e. the angle of incidence of the sun's rays.

For normal incidence the maximum conductivity in this layer should occur at a height of about 26 km, tailing away to one-tenth of its value at 18 and 45 km. At grazing incidence the maximum intensity should occur at a height of 50 km. The height determined from radio measurements is well within these limits.

Day and Night Transmission.

The difference between day and night transmission is readily explained on this theory. Transmission during the daytime is confined to the space between the earth and the lower conducting layer, which we may consider to be practically impervious to the long radio waves. (S. Chapman gives the average conductivity of this layer as 25×10^{-6} C.G.S. units. Radio waves would be entirely absorbed in travelling a very short distance through such a medium.)

At night when the ionizing agent, i.e. the sun's γ radiation, is removed, the ions re-combine, the lower conducting layer disappears and the upper permanent auroral layer comes into play. We must assume, both from radio and auroral evidence, that this has a much better defined under-surface and that it can reflect radio waves at much greater angles of incidence than those which exist in the daytime.

As a consequence we get the irregular interference phenomena which are so characteristic of night transmission and which must be due to slight variations in the height and conductivity of the layer. The night distortion of bearings taken with the ordinary frame type of aerial is also explicable on this theory,* as well as the absence of distortion in daytime. A theory developed on these lines has already been given by one of the authors in the *Radio Review*, and additional evidence of a very convincing nature has also been given by G. M. Wright and S. B. Smith in the same publication.

At the risk of repeating what has already been said in these articles, it will be well to consider this theory in the light of the present evidence, which seems to the authors to supply one of the missing links in the previous argument. Thus the distortion of bearings at night was attributed to the action of high-angle reflected waves polarized with the electric force horizontal and the magnetic force in the vertical plane but perpendicular to the ray. The manner in which this acts in producing distortion of the apparent direction of the ray is sufficiently obvious to require only passing comment here, and may be briefly described by reference to Fig. 116. Let OP be the direction of the ray;

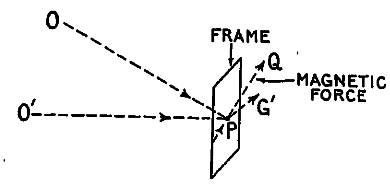

Fig. 116.

then PQ may be considered to be the direction of the magnetic force, the electric force being perpendicular to the paper.

If a vertical frame is erected at P the plane of which is perpendicular to the plane of the paper, it would normally receive no signals from the direction O′P, and would therefore give the correct bearing.

If, however, the ray OP is present the magnetic force PQ is linked with the frame, and a signal will be received notwithstanding the fact that the plane of the frame is perpendicular to the plane of the rays OP and O′P.

The actual position of the frame for minimum signals will depend then on the relative intensities and phase of the rays OP and O′P. It will be observed that the conditions for the production of this distortion are:

(1) That the ray should make an appreciable angle with the earth's surface (i.e. high-angle reflection must be present).

(2) That there should be a component of the magnetic force polarized in the vertical plane.

If either of these factors is absent no distortion of bearing should occur due to this cause. The absence of the distortion in daytime was attributed in the previous paper to the assumed existence of an ill-defined layer present in the daytime which could not reflect high-angle waves at all. The actual existence of such a layer has now been confirmed by the evidence of radio signals and of terrestrial magnetism, and another link

* *Radio Review*, 1921, vol. 2, pp. 60 and 231.

in the argument may be considered to be firmly established.

It may be as well to mention here that bearings taken at great distances at night have been almost invariably correct and free from night distortion. Sufficient explanation of this may be found in the fact that in order that signals may arrive at B, say, with a high-angle incidence, the ray must proceed by many reflections, and the higher the angle of incidence the greater must be the number of reflections. As a considerable amount of energy is lost at each reflection it is probable that the high-angle rays disappear after a few reflections and leave the normal ray undisturbed (see Fig. 117).

Local Variation of Attenuation.

On this theory the attenuation suffered by the wave in daytime is a function of the height of the layer and the gradient of conductivity in the layer. These quantities will vary with the latitude, for they are functions of the angle of incidence of the sun's rays, which depends on the latitude and also on the season. Seasonal changes and also changes with latitude are therefore to be expected.

The form that the variation with latitude will take depends on the two factors: (1) the mean height of the layer, and (2) the gradient of conductivity, as well

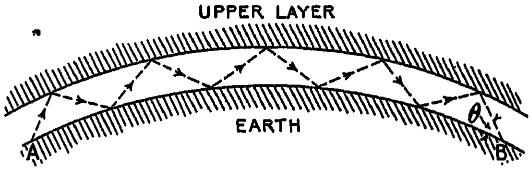

Fig. 117.

as the actual conductivity in the layer. The height should be greater at high latitudes, and the attenuation consequently less on this account. The nature of the change in the second factor is not clear, but it certainly appears to be the determining factor and to increase the attenuation at high latitudes.

It is arguable that the resistivity of the lower layers will be greater because the ionizing agent, i.e. the sun's radiation, will have further to penetrate through the atmosphere when the rays come in at almost glancing incidence, and that the attenuation will therefore be greater.*

The observational material is not sufficient to determine the exact variation of α with latitude, but it is certainly sufficient to suggest that the attenuation is greater at high latitudes and less at lower ones. If it be assumed that the height and nature of the layer is merely a function of the angle of incidence of the sun's rays, there should be a connection between the seasonal change of α and the change of α with latitude. A change from summer to winter should be equivalent to the alteration produced by an increase in latitude. There exists a certain amount of evidence that this is the case. Transmission in winter is worse than in summer, and consequently transmission in high latitudes should be worse than in low ones, as is the case.

* S. Chapman finds that the mean resistivity in the winter, as determined by magnetic observations in England, is considerably greater than that in summer.

Beats.

There can be no doubt that this effect is primarily caused by the interference of signals travelling both ways round the world, for the experiments with the unidirectional or heart-shaped "receiver" cannot be interpreted otherwise. There are, however, so many possible ways in which this interference may be varied so as to cause the beats observed, and so little experimental evidence beyond the actual observation of these beats, that their ultimate cause is still uncertain.

Let us consider the possibilities in detail. Suppose we call the waves which arrive at the receiver by the two great-circle paths, A and B respectively, then we may think of the system comprising the transmitter, earth and receiver, as a gigantic Michelson interferometer. The waves from the source at S follow the two paths SPR and SQR and interfere at the receiver R, and all the experimental evidence allows us to infer is that the relative phase of A and B at R is changing.

When R is not at the antipodes of S, i.e. when the paths SPR and SQR are not equal, the signal arriving by the longer path will be delayed relatively to that which comes by the shorter path, and if the difference is as much as 10 000 km the delay will amount to at least as much as 1/30th second. With high-speed signalling the dots from the two directions will hardly overlap at all and may cause the unreadability which is a characteristic of the beat effect. This effect, of course, will not appear at or close to the antipodes.

Another effect which also depends on the inequality of the two paths, but which does not depend on the speed of sending, is the resemblance which the system bears to a large interferometer. If we could view the electric intensity from the outside of the world we should be able to see a series of interference bands, spaced about half a wave-length apart and roughly forming circles about the antipodes. In the case of absolute symmetry this should be the case, but actually the position and intensity of the bands will be distorted by local variations, light and darkness, etc.

If the position of these interference bands changes, then from the point of view of an observer situated on the surface of the earth this shifting will appear as a waxing and waning of signal strength, in fact as beats. As before stated, the bands are approximately half a wave-length apart. Any variation of the wave-length of the transmitter will therefore cause the bands to contract or expand according as the variation is a decrease or increase of wave-lengths. Hence any change of wave-length of the sources will result in beats at the receiver.

In the case of absolute symmetry the antipodes is a place where all the electric forces are in phase whatever the wave-length; hence the bands contract and expand about this point.

For a given change in frequency of the transmitter the rapidity of the beats will be proportional to the distance of the receiver from the antipodes. If this distance comprises N half wave-lengths, i.e. $d = N\frac{1}{2}\lambda$, and if the wave-length alters by the amount $\delta\lambda$ in the time δT, then any given interference band which is originally at the source will move an amount $N\delta\lambda/2$

and therefore the number of bands which cross the receiver in the time δT is $N\delta\lambda/\lambda$ and the rate of the beats will therefore be $(N/\lambda)(\delta\lambda/\delta t)$. N may be as great as 1 000 so that $(1/\lambda)(\delta\lambda/\delta t)$, i.e. the percentage rate of change of λ, need only be 1 in 1 000 to produce beats of 1 per second.

The effect would therefore be quite observable on alternator or arc stations. This effect is again negligible at or close to the antipodes. Apart from these effects there are two other possibilities depending o ieal variation of the effective electrical length of the two paths: (*a*) the interference bands may shift irregularly about a given mean position, in which case the mean frequencies of the waves along the two paths are equal, but there will be irregular changes of relative phase; and (*b*) the interference bands may wander continually in one direction and never return. This implies a real difference in frequency between the two waves A and B.

With regard to alternative (*a*), this irregular shifting of the bands may be due to any irregular movements in the conducting layer which would tend to shorten or lengthen the effective electrical length of either path; changes in density or refractive index due to ionization, pressure-changes, etc., will all have an effect in altering the time taken.

Alternative (*b*) requires rather more consideration, for a real difference in frequency between the two paths seems rather difficult to believe. The effect is nevertheless possible, but only where there is some movement relative to the earth. The authors think that they are correct in their interpretation of the principle of relativity when they assert that the rotation of the earth as a rigid body cannot introduce any changes in frequency in the two paths as measured by an observer fixed on the surface of the earth. But there may be movements in the upper atmosphere, depending on the rotation of the earth relative to the sun, which might produce effects of this kind. For instance, the Heaviside layer in the twilight regions (at S, say, in Fig. 118) is probably inclined at an angle to the tangent at the earth's surface. This layer acts as a reflector and is moving relatively to the earth's surface at some $\frac{1}{2}$ km per second. The reflection of the ray at this moving mirror will produce a Doppler effect, the amount of which is given approximately by the formula

$$\frac{\delta n}{n} = 2 \sin \theta \sin \phi \frac{v}{c}$$

where v is the linear velocity of the moving layer, i.e. about $\frac{1}{2}$ km per second. If we assume n to be about 20 000, i.e. a 15-km wave, δn comes out at the order of 1/30, i.e. one beat every 30 seconds. This is certainly less than the average rate observed, which may be as fast as slow morse sending.

In connection with the East and West effect the hypothesis was entertained that there was a rapid drift of positively charged particles from East to West. Such a movement, if it existed, would tend to produce a change in the measured frequency for the ray which passes through this drift. The amount of change of frequency can only be guessed at, for it depends on factors which cannot possibly be measured at the earth's surface, but it seems to be within the bounds of possibility that sufficient change might be produced to account for the observed effects.

It may be noted that Mr. Rust has, in a very carefully performed experiment, actually observed these beats in England. Signals from WQK (Long Island, New York) were actually received in England the long way round, i.e. from the East, and were made to interfere with the residual signals from the West, obtained by setting the heart-shaped receiver with its blind spot facing very nearly the normal direction of reception. The authors understand from him, however, that the experiment is by no means easy and it should be carried out only when reception conditions are good and "strays" are not troublesome.

Much remains to be done in connection with this subject, which has very considerable interest from the theoretical point of view, but any experiments devised to determine whether there is a real change of frequency in the two directions will obviously be difficult to carry out.

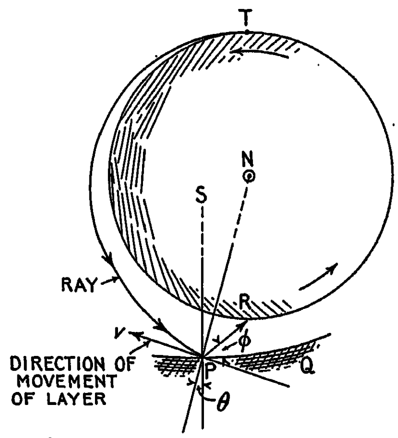

FIG. 118.—Path of ray TPR.

There are some indications that the beat effect is due to the variability in actual transmitted frequency and is not due to any real change in the frequency on the path, for UFT, which is a bad offender in this respect, shows "beats" to a marked degree. Also the fact that beats are not observed on a steady dash suggest that their absence is due to a steadying of the transmitted frequency on a long dash. The receiving station at Perth is close to the antipodes of the American stations, and hence the "beat effect" should be small on these stations.

Actually such effects were difficult to observe on these stations; on the long-wave stations, on which the effect might have been heard, the bi-directional effect only lasted a short time, and the shorter-wave stations, in which the bi-directional effect was of much longer duration, were swamped by X's.

The fact that it could not be definitely stated that beats were heard on these stations rather suggests that the variation of frequency at the transmitter is responsible for these effects.

EAST AND WEST EFFECT.

We have had occasion to note more than once in the course of this paper that transmission in a West to

East direction seemed better than transmission in the opposite direction. By this we mean the undoubted fact that, in every case that was examined, transmission in the West to East direction has been as good as or better than transmission in the opposite direction, whether by day or by night. But it must be very carefully pointed out that this does not necessarily imply that in every case West to East transmission is the better.

For instance, we have evidence that transmission from Europe to Australia on very long waves, e.g. Bordeaux, is better by the short West to East path than by the opposite one, but it would be very risky to state on this evidence that transmission from Australia back to England over the short European path will be unfavourable merely because it is an East to West transmission.

The case of transmission across the Atlantic is the only one in which we have evidence that transmission from America to England, i.e. West to East, is better than transmission over the same path from England to America, i.e. from East to West, and even in this case the difference in attenuation on what may be called the direct and return paths is not very great, and its existence may perhaps be doubted. Except for this case the differences can be attributed, we think, to local and seasonal variations of the attenuation. It must, however, be admitted that it requires considerable ingenuity to do so. If we take a map of the world and mark the routes with the various attenuation constants found for these routes, as in Fig. 119, we shall find that it is possible, except perhaps in the Atlantic, to fit the values in without assuming a different attenuation for a go and return path.

It will be found that except for the isolated case of NBA the high values of α occur in the North Atlantic and low values elsewhere, and although there is apparently a very marked change amounting almost to discontinuity to the East of England, this may be partly due to a change of α with season, for the attenuations to the East of England were observed in the summer months and those to the West in the winter months.

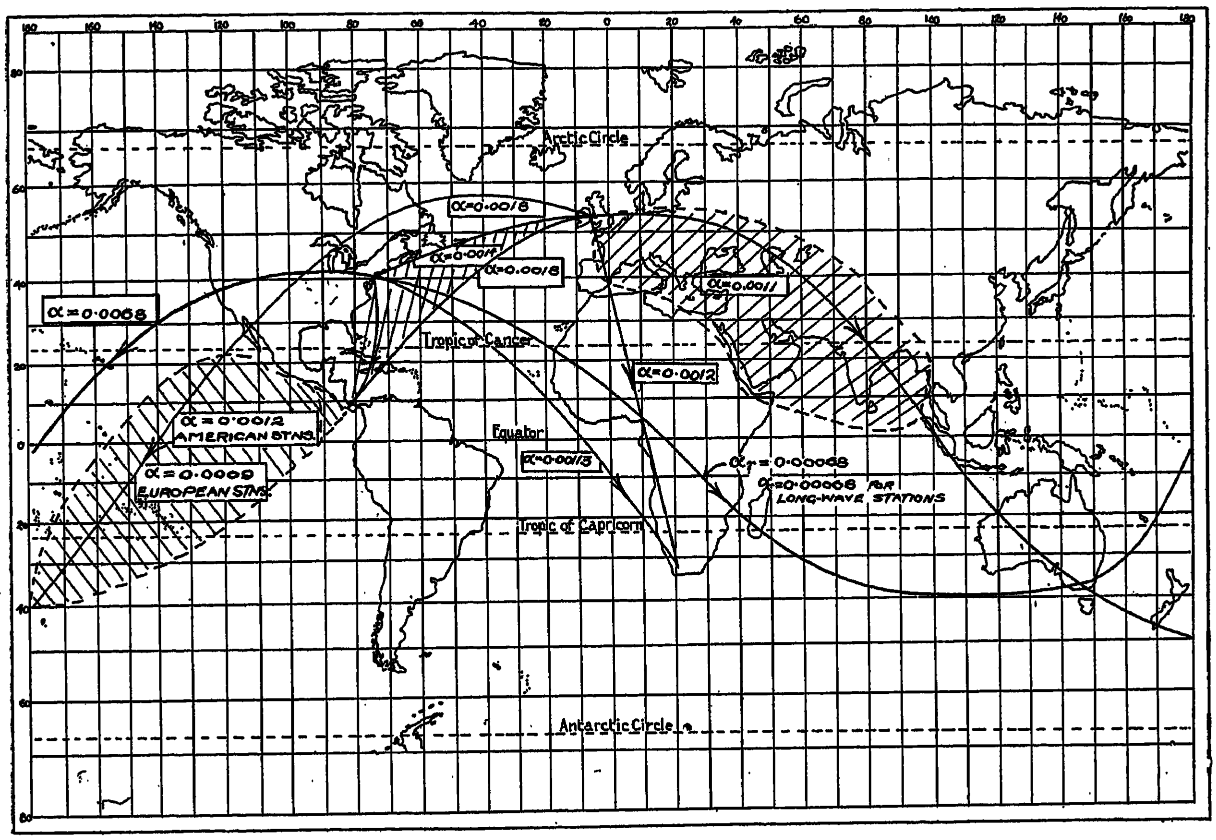

FIG. 119.

On the other hand, it seems more than a coincidence that, in every case so far examined, transmission from West to East has been better than that in the opposite direction.

From the point of view of theory it comes as rather a shock to have to admit the possibility that transmission from A to B, say, may be better than from B to A. Such a possibility seems to contradict the usual reciprocal relations of optics. This is a very general theorem due, we believe, to Helmholtz, which when applied to radio transmission can be translated into radio language in the following terms: If A and B are any two radio stations, however situated, then if they are both working on the same wave-length the E.M.F.

induced in A by unit current in B will equal the E.M.F. induced in B by unit current in A. For example, if we have two equal transmitting stations in England and Australia, then, at a given moment, the field strength produced by the English station in Australia should be equal to the field strength produced in England by the Australian station. If, however, we admit the accuracy of the transatlantic experiments, we shall have an actual case in which this theorem is contradicted.

It must be realized that this theorem is based on the assumption that all effects are linear, i.e. that the state of the field and every relevant quantity in the field (e.g. motion of the ions, electrons, etc.) is a linear function of the currents in the transmitting stations. It is possible to construct an example in which this linear relation is not obeyed, and it therefore follows that a real East and West effect is possible. The authors believe that examples in optics of the violation of this reciprocal relation are well known, but the example chosen here is more relevant to the subject under discussion, and may contain the germ of the explanation of the supposed East and West effect.

When a radio wave passes through a medium containing free ions or electrons these will be set in motion by the electric force. Suppose that the electric force is vertical, and the magnetic force horizontal; then the electric force will set the electrons in motion in a vertical direction, but on account of the vertical motion the magnetic force will produce a force on the electron which is perpendicular to both the magnetic field and this direction of motion, which is therefore in the direction of propagation. When the electric field is reversed the magnetic field is also reversed, the two being in phase, and the force on the electron is still in the direction of propagation. There is consequently a continuously acting force tending to drag the electrons along in the direction of propagation of the ray, and this is in the same direction even when the electromagnetic forces in the wave-front are reversed. The forward drift of the electrons must therefore be a function of the square of the magnetic field strength, and the linear relation no longer holds.

J. J. Thomson has shown how to calculate the actual amount of absorption suffered by a radio wave when passing through a cloud of electrons. As explained, the waves set the electrons with a forward drift the velocity of which can be calculated from the formula

$$c^2 - (c - \omega)^2 = \left(\frac{\lambda}{2\pi}\right)^2 \frac{e^2}{m^2} H_0^2$$

where c = velocity of light,
ω = velocity of drift of the electrons,
λ = wave-length,
e = charge,
m = mass of ion, and
H_0 = magnetic field in the wave-front.

When ω is small compared with c, as is usually the case,

$$\omega = \frac{1}{2c} \cdot \frac{\lambda^2}{(2\pi)^2} \cdot \frac{e^2}{m^2} H_0^2 \text{ (approximately).}$$

These ions have energy, to gain which they have to rob the energy of the wave, and the attenuation constant introduced is equal to

$$\frac{N\lambda^4 e^4}{128 m^3 \pi^4 c}\left(\frac{E}{300}\right)^2$$

where E is the voltage per cm in the wave-front. It varies as the fourth power of the wave-length and the square of the magnetic or electric force in the wave-front.

The way in which this effect may be used to explain the existence of a change of attenuation when the direction of propagation is reversed is as follows: Suppose there is a drift of ions or electrons along the direction of the ray. If the drift is in the same direction as the propagation of the waves, the time it takes for a wave to pass one of the ions or electrons is increased in the ratio of $1 + (v/c)$ to 1, where v is the velocity of drift, and hence, since the absorption is proportional to H^2T^4, we find that the absorption is increased in the ratio of $(1 + v/c)^2$ to 1 (approximately). If the direction of propagation is opposite to that of the drift the attenuation will be reduced in the ratio of $(1 + v/c)^2$ to $(1 - v/c)^2$. It will be observed that it requires very high velocities of drift to produce an appreciable effect, but there is the evidence of auroral effects as well as of magnetic storms to suggest that charged particles may be injected into the atmosphere with velocities comparable with that of light. These particles, if charged, will be deflected by the earth's magnetic field into the polar regions and will be given a West to East or East to West drift according to whether they are negatively or positively charged. It is very improbable, however, that such streams could reach the lower levels of the atmosphere, where the daylight layer is situated.

Again, the effect if it is present should increase very rapidly with the wave-length; now this is characteristic of the East and West effect which occurs at night, for it is only observed on wave-lengths greater than about 16 km and increases very rapidly on longer waves. We should therefore suggest that if this explanation is applicable to all it is only so in the case of night attenuation, and that unidirectional transmission cannot be produced by this cause in the daytime. The direction of the East and West effect which occurs at night suggests that the particles emitted by the sun at high speeds and caught up in the outer layers of the atmosphere are positively charged. The excessive attenuation suffered by the long waves from Bordeaux in the daytime may be an illustration of what may be called the "J. J. Thomson absorption" effect, but it is probably not unidirectional in this case.

In connection with long-wave absorption an experiment was carried out at Carnarvon which unfortunately had a negative result. Signals on a 40-km wave (100 amperes in the aerial) were sent out and listened for in Australia. Not a trace of them could be heard, even though the apparatus used had a fairly high degree of sensitivity. This again suggests excessive attenuations on these long waves.

Earth's Magnetic Field.

In view of the fact that the determining factor of wireless is the attenuation in the upper conducting

layer, and since this depends on the motion of the ions or electrons in the field of the wave, and since finally the motion of these is modified by the presence of a steady magnetic field, we should expect to find a relation between the transmission and the earth's magnetic field.

There are two effects which might be observed. The first is a rotation of the plane of polarization of the wave when transmitted along the magnetic field, and the second a difference of attenuation according to whether the waves are moving transverse to or along the earth's magnetic field. The rotation of the plane of polarization of a plane wave travelling through a medium containing free ions when a longitudinal magnetic force is superimposed is a well-known effect and has been described in various papers, books,* etc., so that the results of such investigations will be assumed.

The full effect of this variation will not be developed unless the mean free life of an ion, i.e. the interval between the collisions, is large compared with the time $T_0 = [m/(eH)]$. The effect is more likely to occur at high levels where the pressure is low, i.e. the mean free life of the ion large, than in the lower levels where it is small.

Accordingly we might expect some such effect in the night but not in the day when the lower layer comes into play.

If θ is the angle of the plane of polarization, then the maximum rate of rotation would be

$$\frac{\delta\theta}{\delta t} = \frac{e}{m}H = \frac{1}{T_0}\dagger$$

or

$$T_0\frac{\delta\theta}{\delta t} = 1$$

which with the value for H in the earth's magnetic field (roughly $0 \cdot 2$ C.G.S. unit) means a complete rotation every $0 \cdot 54$ km.

The evidence afforded by the observations on direction-finding suggests quite strongly that such an effect may exist at night but not in the day, hence we have further evidence that the day-reflecting layer is a region of greater pressure and is therefore lower than the night layer.

The free life, T, of an ion must be less than about 10^{-9} in order that the effect may not be observable in the daytime, so that the pressures at this height cannot be less than about 1/500th of the atmospheric pressure. That is, the height must be less than 35 km (approximately). The lower limit is probably higher than this if all the factors are taken into account.

The other effect shows up as a consequence of the increase of the resistivity of a medium containing free ions in a transverse magnetic field. Numerically the percentage increase in resistivity is *

$$\frac{\delta\rho}{\rho} = \frac{1}{12}\left(\frac{eH}{m}\right)^2 T^2$$

which can be expressed in terms of the time T_0 thus:—

$$\frac{\delta\rho}{\rho} = \frac{1}{12}\left(\frac{T}{T_0}\right)^2$$

which will therefore be a very small quantity unless T, the time between collisions, is large compared with T_0. As before, this effect is not likely to occur in daytime but may occur at night.

Conclusion.

It will be realized that in spite of the enormous amount of material already gained by the authors, due to the indefatigable work of Mr. Tremellen and his assistant Mr. Allnutt, there are still matters, e.g. East and West effect, seasonal and latitude variations, beat effect, etc., about which no decisive statements can be made, and we must look to the future to make good the observational data necessary. We must also leave to the future the framing of a complete theory of "World Transmission of Radio," for the explanations given in this paper must be looked upon rather as suggestions than as final and complete statements of the theory.

Discussion before the Wireless Section, 6 May, 1925.

Admiral of the Fleet Sir H. B. Jackson: I think that the Institution and, in fact, all wireless engineers and wireless scientists, are very much indebted to the Marconi Company for arranging and financing the expedition, and especially to the authors of this paper for the work they did in making the observations and analysing the results. It is very difficult to say which is the most important part of the work that was done—the preliminary work of getting the apparatus designed, made and calibrated and put to very severe test to show that it was trustworthy, or the very hard work that was done by the observers during the tests, or the final analysis of the observations. I imagine that most of the discussion will be rather on the analysis of the results than on the actual work done in obtaining them. The authors have attacked the Austin-Cohen formula, which I think has had a long enough life, and they have analysed the results in detail so as to get the attenuation due to the different causes. The varying attenuations in different parts of the world comprise a new feature which is worthy of very serious study. The fact that the polar areas stop the waves is also of very great interest.

Mr. R. A. Watson Watt: I am particularly interested in the observations on atmospherics, and propose to confine my remarks to that section of the paper which deals with these observations. The convective origin of many atmospherics is now so well established as to justify the hypothesis that all atmospherics arise from convective processes in the atmosphere, and Mr. Tremellen's data form a valuable addition to the evidence supporting the hypothesis. In passing I may say that the wave-form observations of Appleton, Herd and myself confirm the authors' interpretation of the grinder as a series of clicks; this can be seen visually on the cathode-ray screen. The

authors, in differentiating between the click and the crash, refer the click to a single lightning flash, but this does not, of course, preclude a lightning origin for the crash, since sensibly continuous flashes of 5 seconds' duration can be observed visually in latitudes as high as 40° N. The authors indicate that the crash is a product of discontinuities similar to those whose passage forms the most important feature of the meteorology of Western Europe, and they have been fortunate in that their expeditions have taken them into regions where the general "world distribution" is shown up so beautifully as in Figs. 81 to 84, without being overlaid by meteorological phenomena which, although on a sufficiently large scale to affect the greater part of a continent, are still relatively local. In an examination of continuous records of the apparent direction of arrival of atmospherics in Great Britain and Egypt, on which (under the auspices of the Radio Research Board established under the Department of Scientific and Industrial Research) I was actually engaged when the present paper reached me, I was tracing a general "world distribution" following the sun, such as was to be expected from the general principle of convective origin, and which was bound to be traceable if the range of reception for atmospherics were sufficient, but which proves to be very frequently obscured in these latitudes by atmospherics associated with the passage of depressions. Of this a typical case was that of July 12 to 14, 1924, when, as reported elsewhere, a cold front was traced for some 2 000 km across Europe by our recorders. As a matter of history, the convective origin of atmospherics was, apart from direct correlations with observed lightning, shown by Sir Henry Jackson in 1902, and further evidence was collected by the British Association Committee in 1913–15; the solar control was shown by a very high correlation coefficient between apparent direction of arrival of atmospherics and solar altitude found by me in 1922 (in a series of observations which await full interpretation in the light of later observations, in which the complexities due to meteorological disturbances and to the radiogoniometric ambiguity have been reduced). In 1923 Eccles outlined a general distribution following the sun, and Schindelhauer, albeit in a very limited test-period of one month only, in March 1922 found a cum-solar swing of 17° range between 0800 and 1800 G.M.T. Our records show the general type of variation, in a test-period in May, to consist of a stream of atmospherics arriving from an Easterly point about 0900 G.M.T., with a slow swing to a South-Easterly direction of arrival at 1400, an accelerating swing through a Southerly direction at 1800 to South-West at midnight, and a comparatively steady direction of arrival from between South-West and West between midnight and 0800 G.M.T. This stream from the West dies out somewhat rapidly between 0800 and 1000 G.M.T., and is replaced by a new stream from the East. It is of interest to note that our records agree with those of the authors in placing the main source of atmospherics, between midnight and 0700 G.M.T., in South America, and in fact the addition of our mean direction of arrival for February to the 0300 chart of Fig. 85 gives a "three-bearing fix" from base lines of a length which few would have cared to adopt for radiogoniometric locations. It might be profitable to compare individual determinations, and I should be happy to exchange data with the authors if they think it worth while. I am glad to note that the authors agree with what I may now call the British, as opposed to the Continental, view of the average range of reception of atmospherics. I believe that the majority of our atmospherics come from distances over 1 000 km, and that the range of reception on ordinary long-wave sets is not less than the earth's semi-circumference, while, if I do not misinterpret their views, Bellescize, Bureau and others believe that the majority of atmospherics heard originate with a very few hundred kilometres of the receiver.

Dr. R. L. Smith-Rose: On page 936 it is stated that one difficulty in determining the effective heights of aerials is the lack of accurate knowledge of a transmission formula over semi-conducting earth. Whilst admitting the lack of experimental evidence on this point, I should like to suggest that it is sufficiently accurate to take the ordinary Hertzian formula in conjunction with an attenuation factor such as can be obtained from Zenneck's work and a knowledge of the conductivity of the earth. The latter quantity is known from recent measurements at wireless frequencies, and using the value obtained it can be shown that even on a wave-length so short as 450 m the attenuation is only of the order of 9 per cent for a distance of about 50 km. On long waves and the shorter distances involved in measuring effective heights the attenuation would thus appear to be practically negligible. This deduction from theory, however, does not obviate the necessity for some direct experimental evidence on the point. On page 939 it is stated that signals at Girvan are about $1\frac{1}{2}$ times as strong as at Broomfield. Whilst this is correct for N.B. and T., Marion (WSO) only gives 10 to 20 per cent increase in Table 3 and also Figs. 12 and 13. Is this due entirely to slightly shorter wave-length? In Figs. 17–30 ordinates are given in microvolts per metre, whereas in Figs. 31–59 the scale is E.M.F. in an aerial whose effective height is stated as 12 m. Is there any reason why the arithmetic was not completed in the last case while plotting the results? Although for the other transmitting stations the attenuation constant appears to be independent of the wave-length, Bordeaux gives a value of attenuation which is 30 to 50 per cent greater than the mean of that of the other stations for reception both in the Atlantic and the Pacific (see Tables 7 and 8). This is for the wave-length of 23·45 km, whereas when the wave-length was reduced to 18·8 km the attenuation constant was only 7 per cent above the mean for the other stations. This, taken with the report of the experiment tried at Carnarvon on 40 km, would appear to indicate that there is an upper limit to the wave-length which it is advantageous to use for long-distance transmission, this limit being in the neighbourhood of 18 km. Mention has been made of the lack of experimental knowledge of attenuation for overland transmission. For long-distance transmission a value of β, the

attenuation constant due to the land absorption, is obtained on page 983 as = 0·001, and is independent of wave-length. In col. 2 on page 982, however, the value of β is taken as 0·005 to calculate the ratios in Table 12 for the measurements at Broomfield and Girvan. Is this a mere printer's or clerical error or is there another explanation? On page 984, for the purpose of calculating the contribution of earth conduction loss to the attenuation, the resistivity of the earth is stated to fall between the limits of 10^{12} and 10^{13} electromagnetic units, which is from 10 to 100 times that of sea-water. I should like to ask how these values were obtained. The values of resistivity given in standard textbooks for the materials commonly found at or near the earth's surface, vary enormously and are mostly very much higher than the figures quoted. In some recent experiments carried out by Mr. Barfield and myself,* the effective conductivity of the earth was measured by a wireless method at 10 different sites in the South of England between Teddington and Land's End. The resistivities obtained varied from $1 \cdot 9 \times 10^{12}$ to $6 \cdot 4 \times 10^{13}$, and are thus in good agreement with those mentioned in the present paper. The results obtained were found to be fairly independent of the state of the surface of the ground—whether wet or dry, and the nature of the subsoil had no direct influence on the result when, as is usual, soil and vegetation existed at the surface. These values of the resistivity give an attenuation at short distances which is extremely small (only a few per cent) except on short wave-lengths, and, as shown in the present paper, its effect at distances of 3 000 km is only to reduce the strength of signals by 50 per cent. This I consider to be a very important result and it leads to a revision of our ideas as to the previously supposed bad effect of large tracts of land intervening between transmitter and receiver. Now, concerning the attenuation introduced by the earth losses on the waves, it is stated on page 984 that the wave can be pictured as being uniformly distributed between the upper and lower conductors. As mentioned above, calculation from the already known values of the earth's resistivity shows that the contribution of earth currents to the attenuation is negligible. On page 985, however, it is assumed that the energy of the wave passes at such a height from the ground that the introduction of an opaque screen near the earth makes no difference to the energy received at a point well beyond the screen. This would not appear to be quite compatible with the idea of uniform distribution of energy between the earth and the upper layer. Mention is made on pages 959 and 992 of the fact that the twilight line dividing light and darkness acts as a barrier to the passage of waves, examples being indicated in the diurnal variation curves. An excellent example of this effect was obtained on the occasion of the solar eclipse of January 24 last, when some measurements of signal strength were made at four separate stations in this country on some special transmissions from the Rocky Point station. The results obtained were described recently in the *Electrician*,† and the *Electrical Review*,* and were chiefly notable for a signal-strength time curve of the same characteristic shape at each observing station. A rise in signal strength during the eclipse was followed by a decrease to a well-defined minimum strength at a time which corresponded very closely to the passage of the shadow of totality across the great-circle path between transmitter and receiver. This is precisely similar to the effect of the twilight boundary mentioned in the paper. A possible explanation is that the waves passing from the dark to the light side will experience a certain amount of reflection except in the case of normal incidence on the boundary, which would only occur in certain rare circumstances. One side of the dark vertical "slot" in the atmosphere cut out by the eclipse would thus form a partial barrier to the passage of waves, particularly in the upper portions of the atmosphere. If this explanation is correct, one would expect to find that the minimum of signal intensity in the diurnal records of American signals observed in England would be much more marked when the sunrise boundary is passing across the Atlantic than in the corresponding sunset condition. I have not a sufficiently detailed knowledge of the usual occurrences of transatlantic measurements to say if this effect is at all noticeable. On page 976, and particularly on page 994, it is stated that various observations show without any sort of doubt that high-angle reflection is wholly absent in the daytime, and that the effect of reflection begins to be important at distances of about 700 km. I should like to ask for further details of the observations which have established such a point, for apart from the fact that the diffraction curve has departed from the observed values curve at a distance of 1 000 km, I have not come across details of these observations. The general impression I gathered from the paper was that very few, if any, measurements were made at distances below 1 000 km. A careful determination of this minimum distance transpires to be of great importance since it forms the basis of one of the methods of determining the height of the upper layer. In direction-finding several instances can be given of variations of bearings in daylight at much shorter distances than these. One of the most prominent examples is that of Leafield, which at a distance of 80 km has given variations ranging up to 16°. I have always understood that these variations are explained by means of reflected waves from the upper atmosphere and at such a range the angle of incidence must be comparatively small. On pages 994–996 calculations are given of the height of the upper layer. In the first method the above-mentioned minimum distance for reflection is employed to determine the limiting angle (θ in Fig. 114) within which the effective radiation takes place, and the relation obtained is that $d_0 = H/(2\theta_1)$. An arithmetical error seems to have occurred here, for, substituting $d_0 = 380$ and $\theta = 3°$, $H = 39 \cdot 8$, not 32·1 km as given in the paper. In the second method $d\sigma$ is taken as 400 at the top of page 996, whereas if the previously used value of 380 were taken H becomes 39·0, which is practically in complete agreement with the previous corrected

* *Proceedings of the Royal Society*, A, 1925, vol. 107, p. 587.
† 1925, vol. 94, p. 152.

* 1925, vol. 96, p. 214.

value. Now in regard to these calculations, the first is obtained from Watson's formula, which I think was derived on the assumption of a sharply defined reflecting surface, which would give high-angle reflection, as well as the low-angle cases used. The second method as represented by Fig. 115 appears to be a physical representation of the same mathematical problem. The formula employed is, however, derived on the assumption that the reflecting surface is very ill-defined and so high-angle reflection could not occur. It is surely surprising that two methods starting from such contradictory assumptions should give almost identical results for the height of the upper layer. It would also appear as if there is some coincidence in this agreement, since in the first case H is shown as proportional to d_0, which from Fig. 92 and page 982 appears to be approximately proportional to $1/\lambda$, whereas in the second case the final formula on page 996 gives H as independent of λ. Thus if other wave-lengths are used, two separate values of H would be obtained by the two methods. I have made these remarks on the more theoretical part of the paper not in any spirit of carping criticism, but rather to emphasize the limitation of the analysis by reason of the assumptions and approximations which have had to be made owing to the enormous lack of our existing knowledge on this subject. In spite of the magnitude of the experiments there are quite obviously many points and side-issues which must be left for further investigation, and I should like to ask the authors if, for the benefit of future workers who may have to tackle these problems, they would give any hints from their experience as to the most fruitful lines upon which a world-wide study of the propagation of waves might be carried out. It is quite within the bounds of possibility that at some future date an international body may organize such a world-wide research, and we should be proud that such an excellent start has been made by a group of workers in this country.

Mr. E. B. Moullin: This paper describes a wonderfully bold and complete piece of work. There must be many here who, like myself, have often wished to take part in such an expedition and may even have planned the details in imagination. The paper is full of information which is of immediate use in designing transmitting stations, and it contains a great deal of important data respecting the physics of the upper layers of the atmosphere which will be of great assistance to physicists studying these problems. I am particularly interested in the experiments to discover the appropriate value of the constant A_0 in the fundamental transmission formula and I think the information that it is sensibly equal to the theoretical value 120π is of great general importance. At one time the value 60π was often used in America: it seems certain that with a flat and resistanceless earth the correct value would be 120π, but in the presence of an imperfect earth it has seemed not unreasonable to take half this value. I have often wished for facilities to test this constant, because a lack of unanimity in the value used has led to a good deal of confusion in signal measurements. The point is now settled once and for all. It is worthy of notice that if the effective height of an aerial is measured by the Pession method, $h \propto 1/\sqrt{A_0}$, and therefore an error of 2 per cent in the value of A_0 makes only 1 per cent difference in the value deduced for h. With regard to the difficulty of deducing effective height by measuring the E.M.F. induced in a frame, I should like to know if the authors see any objection to the method I have used,* whereby the aerial itself is converted into a three-sided frame whose fourth side is formed by a wire running along, and in contact with, the ground. This method appears to me to remove the difficulty. I am surprised that the calculated values of effective height differ widely from the measured values and I think it would be of interest if we could be told some details of the calculations employed. The method of calculating the attenuation factor resulting from dielectric loss is very interesting. Experiments with well-insulated condensers appear to show that the energy loss per cycle is a constant fraction of the energy stored, as with magnetic hysteresis. This hypothesis has been used in an ingenious manner to deduce the form of the attenuation factor for wave transmission under a Heaviside layer. The discovery of zones in which beats are produced by the interference of the signals arriving by the longer and shorter paths is very interesting. I trust that the Marconi Company will experiment with a very steady station and then cause its frequency to vary in a harmonic manner and so be able to state definitely what is the cause of the phenomenon.

Mr. J. Hollingworth: It is not always appreciated how much preliminary care and consideration are required to obtain results such as those given in the paper, as work of this nature suffers from the severe limitation that, strictly speaking, no repetition of an experiment is possible, and everything has to be allowed for beforehand. The authors have also helped to remove a criticism which has been levelled against this subject, not altogether without justification, namely, that it was all theories and no facts. Personally I am particularly interested in it as I have been working on the subject for the past 18 months. I have for certain definite reasons restricted my measurements to distances not exceeding 1 500 km, so that I can offer no direct comparisons with the long-distance work, but certain general points are of special interest. The first is in connection with Fig. 14, showing the large change in intensity about the October–November period. I was not working during the years referred to in the figure, but last year exactly the same effect occurred not only on transatlantic stations but also at quite short distances and on all wave-lengths observed (minimum 9 000 m). Of course, at these short distances the effect is not always a fall in intensity; it is under certain conditions an equally abrupt rise, but in 1924 practically the whole effect was concentrated into two or three days (October 28–30). I do not know if the authors could determine from their figures whether the change was equally abrupt in previous years, but if so it appears that an almost world-wide watch kept over the period should be of great value. I gather that

* *Journal I.E.E.*, 1923, vol. 61, p. 72.

the authors' opinion of Bordeaux is that it is below normal on the 23 450 m wave and roughly normal on the 18 350 m wave. Dr. Austin, on the other hand, appears to hold the view that the long wave is normal and the short one unusually good, and his view is supported by the French observers. It also agrees with the results I have obtained from four different observing stations in the British Isles, where the signals are now 50–100 per cent greater than would be expected on the analogy of other stations with the same order of wave-length. I am in entire agreement with the statement that single observations should be treated with distrust, as I think the subject has been impeded by elaborate theories built on the results of a few observations at one station of one other station. On the subject of land attenuation I find some difficulty in accepting the authors' figures, at any rate for short distances. I gather that they consider the difference between the transatlantic signals at Girvan and Broomfield—a difference of about 50 per cent—to be due to the extra attenuation over 600 km of land. I think that this requires further verification not confined to these two stations and I should like to quote the following extract from my results. For the past 10 months I have had observations taken periodically of Leafield at Glasgow and Stavanger at Aberdeen. In each case the wave-length, aerial current and aerial heights are practically the same and the distances are respectively 477 km and 495 km, but the former is entirely over land and the latter entirely over sea. The results are averaged and plotted weekly, and in general they do not differ by more than about 5 per cent, though a few "freak" periods lasting about 3 weeks have occurred during which the difference is 100 per cent, after which they fall abruptly into coincidence again. I have not yet sufficient results to give a definite opinion on the height of the upper layer, but a rough approximation gives 50 km during the summer months, rising abruptly to about 65 km at the October change referred to above. I do not agree with the statement on page 994 that high-angle reflection is not present during the day, though certainly a rough calculation shows that the distances in the paper are too great for this phenomenon, which should rarely occur at distances greater than 1 000 km. Space does not permit me to develop the argument fully here, but as a typical example I may say that during the winter months the signals from Nantes at Manchester fall and at Aberdeen rise until at times the latter actually exceed the former although the distance is 60 per cent greater. This is only the most striking of a series of changes which are so systematic that it is impossible to ascribe them to local causes near any particular station.

Mr. R. H. Barfield: As one studies the paper one cannot fail to be struck with the number of directions in which important advances have been made. I think the chief are (1) the establishment of the fact that Watson's reflection formula is in agreement with experience; (2) the recasting of that formula into practical shape far superior to the Austin-Cohen formula; (3) the discovery of the "East-West" effect and of beat phenomena; and (4) the location of the places of origin of atmospherics in a most striking manner. On page 984 the authors distinguish between losses produced by the earth's resistivity, conduction losses in the vegetation, and dielectric losses. Now these are the factors which combine to produce the forward tilt of the wave-front, and the angle of this tilt is obviously a measure of the total losses produced by the surface. Dr. Smith-Rose has mentioned that we have recently made measurements of these forward inclinations at Slough and in many other parts of England, and though many of the measurements were made on surfaces covered with vegetation (e.g. long grass or small bushes) we find, from Zenneck's theory of tilts, that ground resistances in good agreement with the values given by the authors of the present paper are alone sufficient to account for the amount of tilt we obtained. This appears to me to be an experimental demonstration that the earth's resistance is the only appreciable factor in determining the amount of tilt of the wave-front of a horizontally travelling wave, and therefore is alone responsible for producing surface loss. This, of course, ignores the absorbing effect of trees which, being large compared with our apparatus, had to be avoided, but since even these are negligibly small in comparison with the length of waves dealt with in this paper, may not they be classified with smaller vegetation in estimating their probable effect? On page 994 the authors refer to "various observations which show, without any sort of doubt, that 'high-angle reflection' is wholly absent in the daytime." I should be very glad if they would indicate the nature of those experiments.

Prof. E. W. Marchant (*communicated*): Soon after the account given by Mr. Lunnon in the discussion on Mr. Elwell's paper on "Long-distance Wireless Transmission"* of the apparatus he had used for measuring signal strength, one of our research students, Mr. H. D. Sharpe, constructed, in the Laboratories of Applied Electricity, Liverpool, an apparatus similar to that described by Mr. Lunnon. I should like to confirm what the authors say as to the advantages of this method of measurement. We have made a great many tests in Liverpool, using galvanometer methods, and, although these are quite suitable for ranges up to 1 000 miles, the only method which has proved successful for estimating the strength of transatlantic signals has been the one which Mr. Lunnon described and which has been adopted in our later tests. A separate heterodyne circuit has been used in connection with the receiving circuit which not only greatly increases the signal strengths but also enables any very troublesome station to be made less troublesome by tuning the heterodyne circuit so as to make the disturbing station give a very low note. By this means measurements could be made with signals from very distant stations, even when near-by powerful stations were emitting signals of very nearly the same wave-length. In this latitude there is not, of course, the same difficulty with atmospherics that there is in tropical latitudes, and we have not had any serious trouble from them. I should, however, like to say a word or two about

* *Journal I.E.E.*, 1921, vol. 59, p. 677.

the arrangement used by Messrs. Lunnon and Tremellen, in which the "homodyne" signal has been switched on to the receiving aerial, instead of being sent through a dummy aerial circuit. In the process of making measurements we have found it necessary to compare the strength of the locally produced signal and the incoming signal at very frequent intervals. The procedure in making a measurement has been (1) to tune the circuit of the receiver for the signal that has to be measured until it is clearly heard on the telephones connected to our 7-valve amplifier; (2) having started the local oscillators by means of a change-over switch with mercury contacts, rapidly to change the connections from the signal which is coming in on the main aerial to the signal produced by the local oscillator in the dummy aerial circuit, and tune the circuit of the local oscillator until the pitch of the note heard from it is exactly the same as that of the received signal; and (3) to vary the mutual induction between the local oscillator and the receiving circuits until the two sounds are of exactly the same strength. The most troublesome operation is the tuning of the pitch of the signal from the local oscillator to that of the signals being measured, and to do this quickly it is necessary to change-over the mercury switch repeatedly. A great deal depends on the observer. Mr. Sharpe, who constructed the set and made the first measurements, was a good musician. He was able to adjust the local oscillating circuit very rapidly to give the same pitch note as that being produced by the incoming signal and, this having been done, the adjustment of the strength of the local oscillating current so as to make it exactly the same as the received signal was relatively easy. This, I think, was much easier for him to do than for other people with less keen musical ears. Mr. Arnold, who has continued the tests during the past 18 months, is also very quick at adjusting the tune of the local oscillating circuit correctly. I venture to think that it is very desirable that anyone using this method of test should have a good musical ear, and I think that such a person would be able to measure signal strengths, even when atmospheric disturbances and other stations are producing very considerable interference. Our tests have been made on the Annapolis time signals which are sent out at 4.55 (winter time). A Dutch station which comes in very often when the time signals are being measured has very nearly the same wave-length. We have found that by using the separate heterodyne circuit already mentioned and lowering the pitch of the note from the disturbing station, it is nearly always possible to get a fairly accurate measurement of the strength of the Annapolis time signal, when it is audible at all. Both Mr. Sharpe and Mr. Arnold have found that, with great care, they have been able to obtain consistent results on fairly loud signals, such as those from Nantes, within about ± 5 per cent. The order of accuracy of measurement diminishes for weaker signals, the variation in the measurements being about ± 10μV/m for a weak signal with a good operator. I should like to say a word on the measurement of the effective height of the aerial. The three-aerial method described on page 936 would seem to be a very good method of measuring the effective height of the aerial, provided the absorption along the path of the waves to stations A and B from C is similarly absorbent, but it is obvious that if the path from A to C is more absorbent than the path from B to C the measurement will not be exact. We had not the advantage of having three aerials available, and in order to determine approximately the effective height of our aerial we measured the strengths of the signals received from Nantes and Nauen. As particulars were available of the antenna currents and effective heights of the transmitting aerials at these two stations, we were able to estimate the effective height of our own aerial by the Austin-Cohen formula. Using this formula, the effective height, as determined by the average strength of the signal from Nantes, came to 2·3 m, which corresponded fairly closely to the actual height of the receiving antenna above the lead roof of the laboratory on which it was erected. The absorption term in the Austin-Cohen formula reduces the microvolts per metre by 36 per cent only, and, for determinations of the order of accuracy aimed at, the variations in the absorption would not be important. This result was checked by a measurement of the average strength of signal received from Nauen and the agreement was unexpectedly close, the values of the effective height agreeing within 5 per cent. As regards the measurements made on the two stations at Nantes and Nauen, the actual signal-strength variation from day to day is considerable. The extreme variation in the Nantes signals for the month of May, 1924, was from 1 800 to 710 μV/m with a mean value of 1 140 μV/m, the average variation being

± 25 per cent. Approximately the same ratio of variation was observed in the signals from Nauen. The measurements that have been made of the microvolts per metre from Annapolis, distant 5 300 km from Liverpool, show much greater variations. The results for October 1924 are shown in Table A. There have been many days since on which the Annapolis time signal has been inaudible. The effective height of the receiving aerial in Liverpool is, of course, small, and this has made the measurements more difficult than they would otherwise have been. A report on these measurements has been submitted to the British National Committee of Radio Telegraphy, and I am indebted to the Committee for allowing them to be mentioned in this discussion.

Messrs. L. Espenschied, C. N. Anderson and **A. Bailey** (*communicated*) : Upon the date the paper under discussion was read, there was given before the Institute of Radio Engineers in New York a paper reporting upon another long series of measurements of radio transmission upon the lower radio frequencies.* These latter measurements were made in the course of an experimental study of the possibilities of transatlantic radiotelephony across the North Atlantic which has continued for a period of over two years. We have, therefore, been particularly interested in the paper under discussion and in comparing certain of the measurements there given with the corresponding results obtained in the transatlantic radio-telephone measurements.

Diurnal signal characteristics.—We were impressed by the low night-time field strength of transatlantic transmission exhibited in Figs. 5, 6 and 7. We have found the normal condition to be one of *high* night-time fields, the values approaching as a maximum that defined by the inverse-distance law, with lower and more or less constant daylight field strength. Such of our measurements as do show low night-time values occur at times during which disturbances were in progress in the earth's magnetic field. Actually, the effect at such times is not merely to decrease night-time values but to increase slightly the daytime field. We have studied the data in regard to the earth's magnetic field for the dates corresponding to the figures mentioned and find not only that magnetic disturbances occurred during the period for which these measurements were taken, from May 13th to 23rd, 1921, but that they were unusually severe. It appears, therefore, that these curves display abnormal variations accompanying magnetic disturbances rather than typical diurnal variations.

Seasonal variation in daylight field strength.—Fig. 14 shows a very interesting effect in the reduction in the transatlantic daylight signal field which sets in during the late autumn months. This effect has also been observed in the transatlantic telephone measurements. The fact that for the time of year during which this increase in attenuation occurs, viz. the winter months, the transmission path lies quite close to the northern division line between the sunlit and the darkened hemispheres may be of significance in explaining this effect. It should be noted that there are other times during which the transmission path lies in or near the division line between the sunlit and darkened hemispheres, viz. those of sunrise and sunset, and during the night-time of the summer months. All of these cases appear to result in an increase in the attenuation.

Comparison of normal daylight transmission.—In general, a good agreement is found between those measurements for transatlantic transmission given in the paper and the corresponding measurements made in the transatlantic telephone study. In particular, our results agree quite closely with the measurements of Marion (WSO) for transmission across the North Atlantic given in Fig. 26. There is apparently some discrepancy between the data taken at the beginning of the trip on the S.S. "Dorset" and those taken at the end of the expedition on the S.S. "Boonah" (Fig. 24). It will be observed that the field strength received at 5 000 km on the S.S. "Dorset" (Fig. 26) was less than 50 μV/m, while for the same distance on the S.S. "Boonah" it was over 80 μV/m. Evidently part of this is due to the lower daylight values obtaining in the winter time. With respect to the measurements made upon Rocky Point's long-wave transmitter (WQL), as recorded in Fig. 71, we find that those of our measurements which were made at the time the S.S. "Boonah" was receiving WQL across the North Atlantic check very well with the results given. It should be noted, however, that the field strengths measured at this time were abnormally high, due to the fact that transmitter powers larger than normal were in use, the antenna current being approximately 1 000 amperes. The fact that the transmitter antenna current is known to have been changed during the period in which the measurements of Fig. 71 were taken emphasizes the necessity of adjusting the data to constant transmitter power before attempting to interpret them. It is of interest to compare certain of the measurement results given in the paper with those indicated by an empirical formula which expresses the measured results obtained in the North Atlantic radio telephone measurements. The constants of this formula, it will be understood, have been derived merely for the limited physical conditions of the United States–England transmission path and for the frequency range of 15 to 60 kilocycles. The formula is

$$E = \sqrt{(P_{\mathrm{kW}})}\frac{298 \times 10^3}{d}\epsilon^{-[0\cdot005d/\lambda^{1\cdot25}]}$$

In carrying out the transatlantic radio telephone measurements, the powers radiated from three of the stations reported upon in the paper have been determined by a series of comparatively local measurements in the direction of transmission. The radiated power corresponding to an antenna current of 600 amperes is in each case approximately as follows: WQL, 13 kW; WQK, 15·5 kW; and WSO, 9 kW. Using these primary data and substituting in the formula above, remarkably good agreement is found between these calculated values and the observed values, even to distances of 12 000–14 000 km. In the case of WQK (Fig. 24) and WSO (Fig. 26) this represents transmission not only West to East over the North Atlantic but also in the South-West direction when the S.S. "Dorset"

* L. Espenschied, C. N. Anderson and A. Bailey: "Transatlantic Radio Telephone Transmission," *Proceedings of the Institute of Radio Engineers*, 1926, vol. 14, no. 1. See *Bell System Technical Journal*, June, 1925; also *Electrician*, 1925, vol. 95, p. 175.

was in the South Pacific Ocean. Our North Atlantic data do not warrant any differentiation between East-West and West-East transmission. Such differences as have been obtained were within the error which could be attributed to incomplete data on radiated power or insufficient measurements of received field strength.

Source of static.—The paper presents valuable evidence indicating that the tropical belt, and in particular large land areas in it, may be regarded as major sources of atmospherics. The deductions which we have made from a study of the diurnal variations of atmospheric noise, exclusive of the high afternoon static which prevails during the summer months, have led to much the same conclusion. Of interest also, in the paper under discussion, is the apparent movement of the major source of static along with the 3 p.m. meridian. This is in conformity with meteorological data on thunderstorms which indicate that the hours of maximum occurrence of inland or Continental thunderstorms are in most places from 2 to 4 p.m. However, it appears that the time of maximum thunderstorms over the oceans is quite different, occurring between midnight and 4 a.m. The result of this may be to present to long-wave receiving stations in northern latitudes a more or less constant generation of atmospherics along the tropical belt and cause the major factor controlling the diurnal characteristic of atmospherics for a station located in England, for example, to be the transmission efficiency of the intervening medium. This is what is indicated by the analysis we have made of a long series of noise measurements in the transatlantic telephone experiments.

Messrs. H. J. Round, T L. Eckersley, K. Tremellen and **F. C. Lunnon** (*in reply*): Mr. Watson Watt has drawn attention to the divergence of opinion between English and Continental engineers as regards the source of X's, the latter considering that X's originate within a few hundred miles of the receiver. In contradiction of this and in support of the evidence in the paper that the source of X's is generally in the equatorial regions and may in many cases be thousands of kilometres from the receiver, we have some further evidence which was not included in the paper owing to want of space. Measurements made of the relative strength of X's by estimating the strength of signals necessary to read through them at 20 w.p.m., say, when plotted against the distance from the assumed source (obtained from directional measurements), give an attenuation curve of just the same type as that of a station situated at the source, and the presumption therefore is that our estimate of the source of X's is correct.

Dr. Smith-Rose has suggested that the appropriate transmission formula to use for short-distance work in the determination of effective heights is the Hertzian formula multiplied by a suitable ground attenuation factor such as can be obtained from Zenneck's work. We hardly think this is correct, in view of Sommerfeld's theory of the matter. It is shown by him that the Zenneck type of wave, i.e. a surface wave with its appropriate attenuation factor, does not develop its full intensity and is not important at distances which are small compared with the "numerical distance," a quantity defined on page 936. At distances small compared with this, such as are almost invariably used in determinations of effective height, the formula of the Hertzian type alone is appropriate. The difference is probably not of importance except from a theoretical point of view, for at these distances, i.e. at distances small compared with the "numerical distances," the attenuation factor is practically unity, and the difference between the two formulæ can be neglected.

With regard to the relative strengths of the American stations at Broomfield and at Girvan, the ratio of the strengths at Girvan to those at Broomfield is given as approximately $1\frac{1}{2}$. This refers to the average of all the stations received; Marion (WSO) with only 20 per cent difference is certainly anomalous. This anomaly was noted at the time, and a long series of measurements was made with the object of verifying the measurements and eliminating any possible local or temporal reductions in the signal strength at Girvan. This anomaly, however, persisted and is also reflected in the measurements made at Poldhu. The reason for this appears to be connected with the fact that signals do not die away quite uniformly with the distance, and that there is a slight sinusoidal fluctuation, which is shown up in Fig. 89. The nature of this fluctuation is different for different wave-lengths, with the result that over relatively short distances the signal from some stations, e.g. WSO, may appear to die away far less rapidly than those from others, e.g. WII and WGG.

Figs. 31 to 59, of which the ordinates are the actual microvolts, and not as in the case of the others the microvolts per metre, were originally plotted before the effective height comparison had been made. In order to save the labour of re-plotting, tracings were made of the originals in the expectation that they could be altered when the curves were reproduced for the paper, but this alteration was impossible in the limited time available.

The overland absorption factor is, as stated in the paper, a subject of a certain amount of uncertainty, which is perhaps reflected in the method of representing it. There is the choice of expressing the total absorption due to this cause in either the form $e^{-\gamma d}$ or $e^{-\beta d/\lambda}$, where β and γ are considered to be constants. On the whole the latter form is considered to be the more accurate.

The figures $\beta = 0 \cdot 005$ on page 982 and $\beta = 0 \cdot 001$ on page 983 are consistent in view of the variation of β with the distance, for the former refers to short-distance attenuation (600 km in the neighbourhood of the receiver) and the figure $0 \cdot 001$ to long-distance (approx. 9 000 km) transmission.

In the advance copies of the paper there was, unfortunately, an error in the designation of the ordinates of Fig. 94, which should read βd,* where β has the same significance as above, i.e. the total land absorption is $e^{-\beta d/\lambda}$, βd having the limiting value 12. Thus $e^{-\beta d}$ for wave-lengths of approximately 15 km is $e^{-0 \cdot 8} = 0 \cdot 449$, i.e. approximately $\frac{1}{2}$, as stated.

Earth resistivity.—The value of the earth resistivity used in the calculation of earth attenuation, which is of

* Corrected for the *Journal*.

the order of 2×10^{12} C.G.S. units and agrees with Dr. Smith-Rose's results rather than the commonly accepted textbook values which are much higher, was obtained in a variety of ways. The value was deduced primarily from the results of aerial resistance measurements. It is shown in a paper entitled "An Investigation of Transmitting Aerial Resistances" * that the proximity of the earth to a horizontal wire contributes an extra eddy-current resistance per cm of an amount

$$R_0 = \frac{\sqrt{2}}{h}\left(\frac{\rho p}{4\pi}\right)^{\frac{1}{2}} \times 10^{-9} \text{ ohms},$$

where ρ is the earth's resistivity, $p = 2\pi \times$ frequency, and h is the height of the wire above the surface of the earth. From the measurements made of various aerials and screens it was possible to deduce ρ, which is in all cases between 10^{12} and 10^{13} C.G.S. units. The value of ρ at Broomfield was also checked by measuring the high-frequency resistance between two buried plates. As a further check, some experiments to measure the tilt of the wave-front in the waves sent out from Clifden station during February, 1921, may be mentioned. The ratio of the horizontal to vertical electrical force was 1/97, whilst the calculated ratio (from Zenneck's formula) was 1/105, on the assumption that $\rho = 2 \times 10^{12}$ C.G.S. units. This therefore affords a good check on the value of ρ.

The idea that the energy sent out from a transmitter to a distant receiver may follow a path which rises to a considerable height above the earth's surface, like the trajectory of a shell, is not new in radio telegraphy nor is it inconsistent with the idea that the wave is distributed almost uniformly in the space between the earth and the Heaviside layer. With uniform distribution the wave surfaces are perpendicular to the surface of the earth. When, however, the rays follow the high trajectory the wave surfaces, which are perpendicular to the rays, differ only slightly from those in the uniform distribution, as shown in Fig. 97, and the density of energy flow is practically uniformly distributed across the wave surface. The rest of the argument follows from this hypothesis of slightly modified uniform distribution of energy flow.

Sunset effects.—The observed fact that the dividing line between light and darkness acts as a barrier to the long electric waves may, as suggested, be due to a reflection effect at this dividing line, but we are inclined to prefer another explanation. The amount of attenuation is a function of the resistivity of the upper conducting layer, and for the long waves with which this paper deals any increase of resistivity implies a corresponding increase of attenuation. Near the dividing line between light and darkness the sun's rays, which act as the ionizing agent in producing the conductivity of the lower or daylight layer, are removed and the ions rapidly re-combine, producing a consequent increase in the resistivity of the layer at this point, with a progressively increasing local attenuation. This attenuation, however, does not increase indefinitely with the resistivity of the lower layer, for with infinite resistivity the lower layer disappears and brings into play the night layer with its appropriate attenuation. Thus we should expect a transient increase in the local absorption during the transient re-combining period. There are two observed facts which tend to confirm this theory. The first is the observed variation of the time of sunset dip with wave-length, and the second is the absence of sunset or sunrise minimum on short waves of the order of 100 m. With regard to the former observation, it should be observed that the local attenuation referred to is a function of (ρ/λ), so that, as ρ increases, the value of ρ/λ reaches its critical value (for maximum absorption) sooner for short wave-lengths than for long ones, thus ensuring a progressive delay in the occurrence of the sunset minimum as the wave-length increases, which is in accordance with the observations. Again, on sufficiently short waves the attenuation on practically any theory is a function of (ρ/λ), so that if we consider the region where the attenuation decreases with increasing frequency (e.g. between 30 and 100 m) the attenuation must also decrease with increasing resistivity and there is a gradual increase of signal strength from the day to the night value as the twilight band passes between the two stations. The absence of high-angle reflection can be inferred partly from the usual absence of interference effects and directional distortions and partly from the results of observations with the "heart shaped" directional receiver. In the latter case the balance between the current induced in the vertical aerial and that in the frame would not be preserved if there were any high-angle reflection. This does not preclude the possibility of occasions when high-angle reflections may be present even in the daytime, especially in the winter time in high latitudes where conditions approximate to those which obtain at night, but the rarity of these effects suggests that high-angle reflection in daytime is the exception rather than the rule.

The estimate of the distance at which reflection begins to play an important part in the daytime was made by a comparison of the observed attenuation curves and the diffraction curves. The actual attenuation curves have in some cases been extrapolated backwards a little. The figure 700 km is very approximate; all one can say is that 400 km is too small and 1 000 km is too much. Too much stress, therefore, must not be laid on this figure. In using this figure for determining the height of the layer only approximate results were aimed at, and the assumptions which formed a basis for the calculation are also only approximations to the truth. Of the two methods for computing this height the latter (on page 996) should be considered as much more accurate. The two methods are not, in our opinion, contradictory, nor do they even differ to any great extent. Both methods involve the assumption that the layer is ill-defined, so that reflection is confined to practically glancing incidence; the former, however, assumes further that the energy within a cone of angle θ, where θ is so chosen that the reflected ray comes down at 700 km distance, is uniformly distributed over the space between the earth and the Heaviside layer. To emphasize the fact that

* *Journal I.E.E.*, 1922, vol. 60, p. 581.

the assumption of an ill-defined layer is involved in this calculation, we would draw attention to the statement at the top of the first column on page 995, where it is stated that "in view of the fact that high-angle reflection is absent, let us suppose that the energy radiated within a cone of angle θ (see Fig. 87) is reflected, but that higher-angle transmission than this is absorbed or, anyhow, not reflected," which is a direct consequence of the assumption of an ill-defined layer. The two methods would be in exact agreement if instead of assuming that θ was a constant for all wave-lengths, i.e. that the distance at which reflection becomes appreciable is also independent of λ, we assumed that $\theta = H/8\lambda$, an assumption which, in view of the indefinite nature of this distance, is perfectly justifiable. By reversing the process we may use the second formula to determine θ and so find that higher-angle reflection than about 3° on a 15-km wave-length is absent, confirming our previous estimate that high-angle reflection is in general absent in the daytime.

It was hoped that the paper itself would suggest the lines of future research; one obvious requirement is the extension of the work to shorter wave-lengths. The region below 5 000 m has not been studied with any degree of thoroughness, and we have theoretical evidence that a change in the nature of daylight transmission occurs about this wave-length and a further change on ranges from 50 m downward *; an investigation of field strengths on these wave-lengths would therefore be of the greatest value.

In reply to Mr. Moullin, the method of using a frame with a wire running along the earth as the fourth side for the absolute determination of effective height should not, we think, be open to any objection unless the difficulty of measuring the current at a symmetrical point be serious. Thus it is usually necessary to ensure symmetry by measuring the current at the centre of the lower wire of the frame. This, we think, would be impossible in Mr. Moullin's case, but the necessity for symmetry is very much reduced in this case and we doubt if it is a serious point. The method of calculating the effective heights was one in which the distribution of the current in the aerial was assumed to be sinusoidal with a node at the end of the aerial wire; the effective height was then determined from the relation

$$\text{Effective height, } h = \frac{1}{EI_0}\int Eidh$$

where E was assumed to be the electric force (asssumed independent of h), I_0 the current at the base of the aerial, and i the current at any point h in the aerial. With the ever-increasing interest in short waves we are afraid that it may be a long time before we are able to test whether the beats observed in the neighbourhood of the antipodes are due to a variation in the frequency of the transmitter or whether they must be attributed to one of the other causes suggested in the paper.

In reply to Mr. Hollingworth the sudden change in the received intensity at the end of October or beginning of November was originally noticed in the Clifden–Glace Bay services. This period during which it was practically impossible to get signals, was noticed regularly every year; the dates on which the most intense reduction were observed were in the neighbourhood of November 13th. There is a similar weak period, but not quite so marked, in the Ongar–Glace Bay service (GB, $\lambda = 7\,800$) at about a symmetrical time in the early part of the year, i.e. about the beginning of March, which may perhaps be attributed to the same cause, whatever it may be.

All our measurements show an abnormally high attenuation on Bordeaux's longer wave, to an extent we should consider outside the limits of experimental error, and indicate that the 18·35 km wave is normal. This, of course, depends on how one defines "normal" transmission. On the basis used throughout the paper, however, the long wave is certainly the abnormal one.

The estimate of land absorption based on the relative strengths of signals from a given station at two ranges, one of which includes more land than the other, should, we think, bear more weight than one which involves the use of two different and differently situated stations each, as were used by Mr. Hollingworth. The former estimate is freed from any assumption as regards the effective radiation from the given station or stations, whereas the latter is not. Moreover, the estimate in the particular case referred to does not rest on the basis of the observations of two stations only, but has the additional evidence of the measurements made on Clifden, Glace Bay and Rocky Point (WQK), the latter two being measured at Poldhu and Broomfield simultaneously, the ray to Poldhu being also practically wholly over sea.

In the case of GB signals the difference was very marked indeed, the signals at Poldhu being as much as 3·8 times stronger than those received simultaneously at Broomfield. The atmospheric absorption should in this case only account for an increase of 1·4 times the signal strength. The case for a very considerable reduction due to land absorption is, we consider, quite strong.

Mr. Hollingworth does not indicate how he arrives at his estimate of the height of the daylight reflecting layer, but we agree with him that there is apparently evidence of an increase of height in the winter time, although our estimate of the change is not so great as his. The reply to Mr. Hollingworth's criticism with regard to daylight interference effects is, we think, contained in our reply to Dr. Smith-Rose.

The point raised by Mr. Barfield is a little difficult to discuss in view of our present ignorance of the mechanism of dielectric loss. The experiments on this loss made in connection with the investigation of transmitting aerial resistances showed clearly that it was the *vertical* electric force which was responsible for this loss, and suggests that the energy in this case was transmitted practically horizontally over the earth's surface to the place where it is lost. With regard to the transmission losses in big structures on the earth's surface, the same argument would apply. The observations of the tilt of the wave-front over grassy surfaces would suggest that the loss under such

* See *Nature*, 1925, vol. 116, p. 924.

conditions is purely resistive, and the dielectric loss, if it is present, should be attributed to the larger structures such as trees, bushes, houses, etc. The question with regard to high-angle reflection has already been dealt with.

In reply to Messrs. Espenschied, Anderson and Bailey, who raised the question of diurnal signal characteristics, with regard to the contrast between day and night signals it must be remembered that the results obtained by us across the Atlantic refer to very much longer waves than those employed in the transatlantic telephony experiments, where the difference between day and night values are much greater. It should be noted that the particular results referred to are rather in the nature of exceptions and that over very great distances the attenuation constant at night appears to be approximately one-half the day-time value in the range of wave-lengths 6–25 km (see page 987). It is interesting to note the apparent connection with disturbance of the earth's magnetic field, but a large amount of material is necessary before a correlation between the disturbance of the earth's magnetic field and the attenuation of radio signals can be established definitely.

Comparison of normal daylight transmission.—It is satisfactory to note the agreement between the measurements made by two different measuring instruments. It might be well to correct the impression which might be suggested by the comments of Messrs. Espenschied, Anderson and Bailey, viz. that we have neglected to take account of variations in transmitted power. There are, no doubt, some cases where the necessary information was not forthcoming, but all the results obtained on the S.S. "Dorset" were, by the courtesy of the Radio Corporation of America, who gave us copies of the transmitting logs, reduced to constant transmitting current. Similar reductions to constant transmitting current were made in the case of Carnarvon, Clifden and Glace Bay, and the agreement of the results obtained from these with those obtained from other stations suggests that the effect of variations of transmitted energy from the latter cannot have been of very great importance when averaged over the long period of reception.

The variations of the transmitted power from the American stations during the return voyage on the S.S. "Boonah" may account for the rather wide scattering of the values of α obtained. The empirical formula developed by Messrs. Espenschied, Anderson and Bailey is certainly in good agreement with the results obtained, but, as stated in the paper, it has the disadvantage of being purely empirical, so that very little information can be gleaned from the fact that the falling-off of signal strength can be expressed in this manner. There are probably a large number of different empirical formulæ which would agree with the observations with the same degree of accuracy, so that too much stress must not be laid on any particular one.

THE REVERSED-ROTATION SHORT-CIRCUIT TEMPERATURE-RISE OF INDUCTION MOTORS.*

By J. H. R. NIXON, Associate Member.

(*Paper first received* 1*st January, and in final form* 7*th May*, 1925.)

SUMMARY.

The paper analyses a method of testing induction motors for temperature-rise, used mainly when means of loading are not available.

It is shown that the results of such tests are of the greatest value when studied in conjunction with certain design features of the machines, and simple expressions are developed which enable the test-measurements of heating to be converted to probable values of full-load temperature-rise.

The conclusions reached are compared with the results of actual tests.

The problem of obtaining and dissipating large quantities of energy renders the full-load temperature testing of large machines at makers' works an undertaking of great practical difficulty, and recourse has generally to be made to some form of equivalent heat test by which the losses of the machines are simulated without undue expenditure of energy. It is seldom, however, that such equivalent tests produce direct indications of the normal heating under full-load conditions, and the results must be appreciated with regard to the nature and distribution of the losses in addition to the manner of cooling, in order to obtain a true estimate of their meaning. The paper is an attempt to show how the results of an equivalent test applied to induction motors may be interpreted, by simple and practical methods, into reasonable indications of full-load temperature-rise.

The test, known as the "reversed-rotation short-circuit test," is made by driving the rotor at normal full-load speed in opposition to the direction of the rotating field due to the magnetizing current in the primary windings, that is, in the opposite direction to that in which it would tend to run normally. The secondary windings, which are usually on the rotor, are short-circuited and a supply voltage, of the same periodicity and number of phases as that for which the primary windings are designed, is impressed upon the stator windings (assuming they are primary), and the voltage is adjusted to a value which will circulate full-load current in these windings. The machine is run under these conditions until the temperatures are steady, when observations of the temperature-rise are carried out in the usual way. It is evident that since the rotor is running at its normal speed, the conditions of ventilation in the machine will be the same as are present in service, provided the normal air supply is available for the test, which, with the exception of special cases, should present no difficulty. Furthermore, it follows that the rotational losses due to windage and friction will not differ greatly from the values obtained in service.

The remaining losses which appear in the form of heat are :—

(1) Stator copper loss ;
(2) Stator iron (or core) loss ;
(3) Rotor copper loss ;
(4) Rotor iron (or core) loss ;

and these will be considered in separate relationship to their full-load values.

(1) *Stator copper loss.*—This is made up of I^2R and eddy-current losses, each dependent upon the current circulating in the stator windings. Since this current is adjusted to its full-load value, the loss in the copper during the test is equal to the loss at full load.

(2) *Stator iron loss.*—The rotor windings are short-circuited and consequently a comparatively low voltage is required at the stator terminals to circulate full-load current in the stator windings. In fact this voltage corresponds to the impedance voltage of the machine.

Let E_{ph} = the normal pressure per phase for which the stator windings are designed.
Z' = the total equivalent impedance (stator and rotor) per phase.
I_{fl} = the normal full-load stator current per phase.
K = a constant.

Then, with short-circuited secondary

$$\frac{E_{ph}}{Z'} = KI_{fl}$$

whence

$$I_{fl}Z' = \frac{E_{ph}}{K}$$

Now by the well-known fundamental relationship of voltage and magnetic flux

$$E = 4 \cdot 44 K_1 f_1 T_2 \Phi \times 10^{-8}$$

That is, in a given machine and at normal frequency $E = K_2\Phi$, where K_2 is a constant.

Hence the main flux Φ and consequently the magnetic densities due to the main flux are directly proportional to the applied voltage E. In the test the applied voltage is E_{ph}/K; therefore the main flux is equal to

* Thesis accepted in lieu of the Associate Membership Examination.

Φ/K and the magnetic density due to this flux is equal to B/K, where B is the normal density due to Φ.

Now the iron loss is made up of hysteresis and eddy-current losses, and varies with the magnetic density in accordance with well-known laws as follows:—

Hysteresis loss varies as $B^{1\cdot 6}$.
Eddy-current loss varies as B^2.

From this, the iron losses in the stator core and teeth due to hysteresis and eddy currents under the conditions of this test may be written, relatively to the losses at full load, as $(1/K)^{1\cdot 6}$ and $(1/K)^2$ respectively.

The value of K for an average machine is 5, and taking this value as an example the above ratios are $1/13\cdot 2$ for hysteresis losses and $1/25$ for eddy-current losses, from which it is evident that the iron loss in the stator is small enough to be neglected from the point of view of its influence upon the temperature-rise.

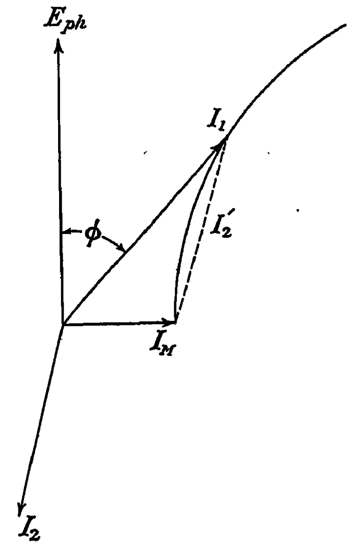

FIG. 1.—Stator and rotor currents at full load.

In addition to the above-mentioned loss a certain amount of iron loss is produced in the stator teeth by stray flux due to current flowing through the windings. This loss is not easy to calculate and, from the point of view of heating, may be neglected, particularly as it is also present at full load.

(3) *Rotor copper loss.*—The losses in the rotor copper exceed the losses at full load for the following reasons:—

(*a*) The current in the rotor (secondary) windings is, by reason of the windings being short-circuited, greater than full-load current.

(*b*) Eddy currents exist in the copper which are not present at full load.

(*c*) Following upon the increased loss and the consequently increased temperature, the final resistance of the windings is higher.

These effects will be discussed in detail, as they constitute a predominating factor in the results obtained.

(*a*) The relationships between stator and rotor currents are made clear by Figs. 1 and 2 which are drawn to the same scale, the stator current I_1 having the same value in each case. Now the resulting magnetizing effect of the stator and rotor currents I_1 and I_2 is equal to the magnetizing effect of the current I_M. Under the conditions of test, I_M is negligible and the magnetomotive force of the rotor current may be regarded as equal and opposite to the magnetomotive force of the stator current, that is to say, $I_1 = I_2'$, where I_2' denotes the rotor current in terms of the stator winding.

If $\cos\phi$ is the full-load power factor of the motor, and I_M is assumed to be 90 degrees out of phase with E_{ph}, then, by the geometry of Fig. 1,

$$I_2'^2 = I_1^2 + I_M^2 - 2I_1I_M\cos(90-\phi)$$

Let $I_M = K_3I_1$, where K_3 is a constant,

then $$I_2'^2 = I_1^2 + K_3^2I_1^2 - 2K_3I_1^2\sin\phi$$

i.e. $$I_2'^2 = I_1^2(1 + K_3^2 - 2K_3\sin\phi)$$

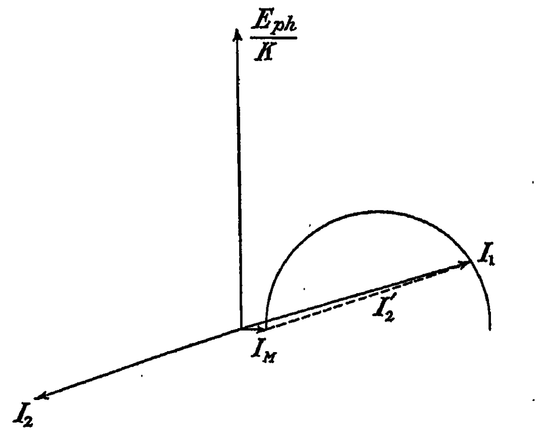

FIG. 2.—Stator and rotor currents at short-circuit.

Now in the test $I_2' = I_1$, hence the ratio of rotor current to its value at full load is

$$\frac{I_1}{I_2'} = \frac{I_1}{I_1\sqrt{(1+K_3^2-2K_3\sin\phi)}} = \frac{1}{\sqrt{(1+K_3^2-2K_3\sin\phi)}}$$

and, since the loss is proportional to the square of the current, the increase in rotor copper loss from this source is in the ratio

$$\frac{1}{1+K_3^2-2K_3\sin\phi} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

It may be noted in passing that this ratio is approximated to very closely by the expression $(1/\cos\phi)^2$, but the latter is likely to give incorrect results if used indiscriminately.

(*b*) *Loss due to eddy currents.*—When the motor is developing its full-load torque at its natural speed, the slip is small and therefore the frequency of the induced current in the rotor windings is low; but in the test the rotor is driven at full speed in opposition

to the rotating field of the stator, hence the frequency of the induced current is practically double that of the supply frequency, and, whereas at full load the eddy currents in the rotor copper produce a loss which is negligible, the loss at double the line frequency is likely to be formidable. The loss from this source may be calculated readily from the curves due to A. B. Field.

(c) *Loss due to increased resistance.*—To take this loss into account is probably a refinement which is hardly justified in view of the approximations necessarily involved in a test of this nature, but it can be so quickly estimated that there is little or nothing to be gained by ignoring the extra loss involved. According to B.S.S. No. 72 of 1917, the temperature coefficient of the change of resistance of copper is to be deduced from the formula

$$\frac{1}{234 \cdot 5 + t_0}$$

where t_0 is the initial temperature of the winding in degrees C.

Then if R_t = the final resistance,
R_0 = the initial resistance at t_0 °C., and
t = the temperature-rise in degrees C.,

$$R_t = R_0\left(1 + \frac{t}{234 \cdot 5 + t_0}\right)$$

i.e.
$$\frac{R_t}{R_0} = 1 + \frac{t}{234 \cdot 5 + t_0}$$

This equation can be conveniently expressed in the form of a chart (Fig. 3) which enables the increase in resistance for a given temperature-rise to be read at a glance.

For example:—*It is required to find the increase in resistance of copper the temperature of which has been raised by 26 deg. C. from an initial temperature of 25° C.*

Read horizontally from the ordinate at 25° C. to the point of intersection with the lower curve, and from this point proceed vertically to the given temperature-rise on the inclined scale. The point thus found is the ordinate of resistance increase, which may be read directly from the appropriate scale by horizontal projection. The result in the example is 1·1, i.e. 10 per cent increase in resistance above that measured at the initial temperature.

(4) *Rotor iron loss.*—The losses in the rotor at full load are inappreciable, but they become of greater magnitude when the rotor is run as in the test. Although the main flux does not link with the rotor, the leakage flux due to the rotor current threads mainly the rotor teeth and is of double the line frequency, consequently the ensuing loss is not inconsiderable. Unlike the corresponding loss in the stator teeth this is not present at full load, due partly to the different value of the current but mainly to the great difference in frequency of this stray flux between normal slip frequency and that of reverse rotation. However, this iron loss is exceedingly complex and difficult to calculate accurately. For practical purposes it may be assumed to be equivalent to the loss in the teeth at 20 to 25 per cent of normal density calculated at a frequency which is double that of the supply. The lower percentage is applicable to machines having few poles, and increases slightly with the number of poles.

Influence of the Rotor Losses upon Stator Temperature.

From the foregoing considerations it would be expected that the temperature measurements made on this test would show the average rotor temperature-rise to be higher than at full load, and the average stator temperature-rise to be lower. This would be true of a machine having pure axial ventilation and with the air paths so disposed that air which has cooled the rotor does not influence the temperature of the stator. However, the most common arrangement is that which takes advantage of the natural draught of the rotor and results in a combination of radial and axial ventilation in which a large proportion, if not all, of the air which cools the stator first passes through or by the rotor. The extent to which this occurs will influence the temperature-rise of the stator over and above that due to its losses alone.

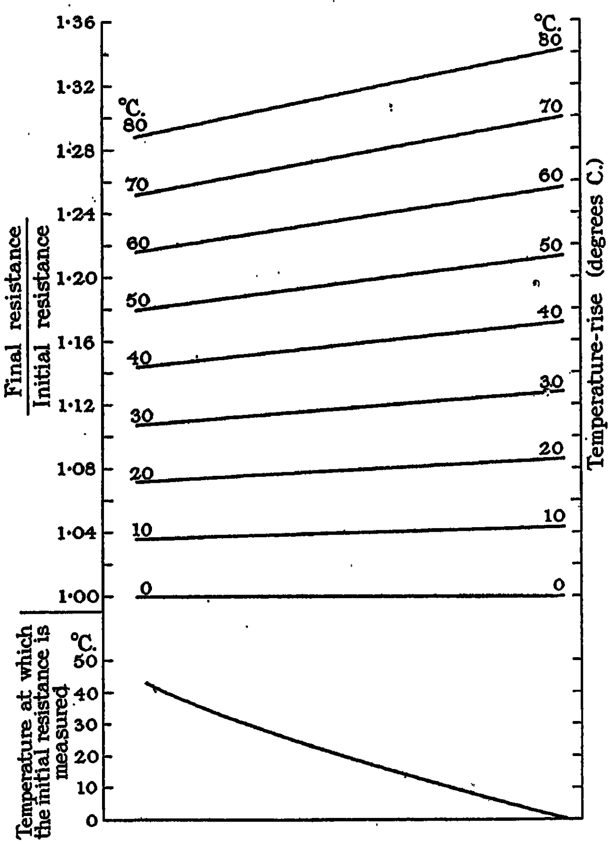

FIG. 3.—Temperature-rise by resistance.

It is therefore important to have an approximation of the proportion of stator cooling air which has received heat from the rotor prior to entering the stator, in order to estimate the effect of the rotor excess losses upon the

heating of the stator. Suppose, for example, that the whole of the stator cooling-air first passes through the rotor, then at full load the air entering the stator is raised in temperature by an amount proportional to the full-load losses occurring in the rotor. Now on the short-circuit test this is raised by a further amount on account of the extra losses in the rotor, and the temperature-rise above atmospheric temperature of the stator carrying the same loss under each condition would be higher on short-circuit by that amount.

Let T_0 = temperature of the atmosphere surrounding the machine under test.
T_1 = temperature of the air leaving the rotor at full load.
V = proportion of stator cooling-air which has received heat from the rotor.

Let it be assumed that the temperature of the air passing the rotor is raised in proportion to the losses carried by the rotor.

Then at full load the temperature of the air entering the stator is

$$VT_1 + (1 - V)T_0$$

If W_{2fl} = rotor loss at full load and W_{2sc} = rotor loss at short-circuit, the temperature of the air leaving the rotor at short-circuit is

$$\frac{W_{2sc}}{W_{2fl}}T_1$$

and the temperature of the air entering the stator is

$$V\frac{W_{2sc}}{W_{2fl}}T_1 + (1 - V)T_0$$

The primary concern is the amount by which the temperature of the air entering the stator at short-circuit exceeds that at full load, as this may be regarded as a definite addition to the temperature-rise of the stator.

Increase of temperature

$$= \left[V\frac{W_{2sc}}{W_{2fl}}T_1 + (1 - V)T_0\right] - [VT_1 + (1 - V)T_0]$$

$$= V\frac{W_{2sc}}{W_{2fl}}T_1 - VT_1$$

$$= VT_1\left(\frac{W_{2sc}}{W_{2fl}} - 1\right)$$

Now since T_1 depends for its actual value upon W_{2fl}

$$T_1 = K_4 W_{2fl}$$

where K_4 is a constant, and, by substitution, the increase of temperature

$$= V(K_4 W_{2fl})\left(\frac{W_{2sc}}{W_{2fl}} - 1\right)$$

$$= VK_4(W_{2sc} - W_{2fl})$$

That is to say, the temperature-rise is proportional to $V(W_{2sc} - W_{2fl})$ and the loss obtained by this expression will have the same effect upon the stator temperature-rise above atmosphere as though it occurred in the stator itself. It may therefore be assumed to be located in the stator and form an artificial part of the stator losses.

Effect of the Separate Losses upon the Temperature-Rise of the Stator.

If the copper were so insulated from the iron that no flow of heat could take place between copper and iron, or vice versa, the temperature-rise of each element would be proportional to its own losses, independently of the other. Thus, with no iron loss and full copper loss, whilst the copper would reach its normal temperature-rise, the iron would not rise above the temperature of the air passing by it. In practice, an exchange of heat does take place between copper and iron, according to the type of insulation used, and this insulation may be broadly divided into two classes, viz. that used for low-tension and for high-tension windings. The ordinary insulation adopted for low-tension windings offers but little resistance to the flow of heat, and this naturally results in fairly even temperatures throughout the stator, whatever the distribution of the losses. If W_{fe} and W_{cu} denote the core loss and copper loss respectively in a low-tension stator, the temperature-rise measured at any part of the stator may be regarded as proportional to $(W_{fe} + W_{cu})$.

Now on short-circuit with reversed rotation the value of W_{fe} is negligible, and it has been assumed that the stator carries a loss equal to $V(W_{2sc} - W_{2fl})$.

Hence if t_s = the temperature-rise of the stator on short-circuit and t_f = the temperature-rise of the stator on full load

$$\frac{t_f}{t_s} = \frac{W_{cu} + W_{fe}}{V(W_{2sc} - W_{2fl}) + W_{cu}}$$

and the probable value of

$$t_f = t_s\left[\frac{W_{cu} + W_{fe}}{V(W_{2sc} - W_{2fl}) + W_{cu}}\right] \quad . \quad . \quad (2)$$

The type of insulation used for high-tension windings affords a somewhat more special problem, for the thickness of the insulation between copper and iron is such that a considerable heat gradient may exist, and the probable temperature-rise at full load needs to be estimated in a slightly different way.

Let t_{cu} = temperature-rise of the copper at short-circuit (measured on the end windings).
t_{sfe} = temperature-rise of the core at short-circuit.
t_{ffe} = temperature-rise of the core at full load.
t_1 = temperature-rise of the cooling air above normal.

Now the iron core is receiving heat from the cooling air (preheated by the rotor) and from the stator copper.

Temperature-rise of iron due to copper loss in winding $= t_{sfe} - t_1$.

Now in watts, say, this is equivalent to $\frac{t_{sfe} - t_1}{t_{cu}}W_{cu}$.

Then the iron temperature-rise at full load relatively to the temperature-rise at short-circuit

$$= \frac{t_{ffe}}{t_{sfe}} = \frac{W_{fe}}{[(t_{sfe} - t_1)/t_{cu}]\,W_{cu}}$$

and

$$t_{ffe} = \frac{W_{fe} \times t_{sfe}}{[(t_{sfe} - t_1)/t_{cu}]\,W_{cu}} \quad . \quad . \quad . \quad (3)$$

The temperature-rise of the copper at full load would be

$$t_{ffe} + (t_{cu} - t_{sfe}) \quad . \quad . \quad . \quad . \quad . \quad (4)$$

525-volt 50-cycle three-phase circuit, and the average temperatures observed were as follows :—

After 6 hours at full load :—

Stator	56·5° C.	Rise = 38·5 deg. C.
Rotor	37·0° C.	Rise = 19·0 deg. C.
Room	18·0° C.	

After 6 hours at reversed-rotation short-circuit :—

Stator	55·0° C.	Rise = 36·0 deg. C.
Rotor	54·0° C.	Rise = 35·0 deg. C.
Room	19·0° C.	

TABLE.

Brake horse-power	150	250
Speed, in r.p.m.	485	225
Voltage	440	400
Frequency, in cycles per sec.	50	50
No. of phases	3	3
Full-load stator copper loss, watts	3 610	7 140
Full-load stator iron loss, watts	4 330	4 350
Full-load rotor copper loss at room temperature, watts	2 600	3 900
Estimated full-load power factor	0·87	0·77
Steady temperature-rise after reversed-rotation short-circuit run with full-load stator current—		
Stator	31 deg. C.	56·5 deg. C.
Rotor	40 deg. C.	54·0 deg. C.
Temperature of surrounding air	17° C.	20·0° C.
Multiplying factors for excess rotor loss—		
By excess current	1·33	1·61

By resistance	1·16	1·213
Total rotor copper loss, watts	5 770	13 200
Iron loss in rotor teeth, watts	420	580
Total rotor loss in test, watts	6 190	13 780
Full-load rotor loss, watts	2 780	4 150
Calculated full-load temperature-rise of rotor (by Equation 5)	18 deg. C.	16 deg. C.
Calculated full-load temperature-rise of stator (by Equation 2) [$V = 1$]	35 deg. C.	39 deg. C.
Measured full-load temperature-rise of rotor	17 deg. C.*	19 deg. C.
Measured full-load temperature-rise of stator	31 deg. C.*	40 deg. C.
Temperature of surrounding air	18° C.	21° C.

* Measured after a run in which the load averaged 95 per cent of full load.

TEMPERATURE-RISE OF THE ROTOR.

This may be simply deduced from the ratio of the losses at short-circuit to those at full load in proportion to the short-circuit temperature-rise. Let this latter be t_{2sc}. Thus the probable full-load temperature-rise is

$$t_{2sc}\frac{W_{2fl}}{W_{2sc}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

APPLICATION OF THE METHOD TO AN ACTUAL CASE.

Heating tests were carried out upon a 100-b.h.p. induction motor designed to run at 720 r.p.m. on a

The following data are deduced from no-load and locked-rotor short-circuit readings in addition to resistance measurements :—

Magnetizing current at normal pressure	40 amps.
Full-load stator current per phase	106 amps.
Full-load stator copper loss	2 720 watts
Full-load stator iron loss	2 710 watts
Estimated full-load power factor	0·85
Full-load rotor copper loss	2 030 watts at 19° C.

ROTOR LOSSES ON SHORT-CIRCUIT.

(*a*) Increase above full-load copper loss by excess current (by Equation 1) :—

$$\left(K_3 = \frac{40}{106} = 0 \cdot 378\right)$$

$$\frac{1}{1 + 0 \cdot 378^2 - (0 \cdot 756 \times 0 \cdot 527)} = 1 \cdot 35$$

(*b*) Increase by eddy currents at 98 cycles per sec. (from Field's curves) = 1·36

(*c*) Increase by resistance (from Fig. 3) = 1·14

Total rotor copper loss .. .. = 2 030 × 1·35 × 1·36 × 1·14 = 4 250 watts.
Allowance for iron loss in teeth .. = 260 watts.
Total rotor loss on short-circuit .. = 4 510 watts.

The probable full-load temperature-rise of the rotor may now be roughly estimated as (2 030/4 510) × 35 deg. C. = say 16 deg. C.

From Fig. 3 the increase in resistance from cold = 1·06.

Hence full-load rotor loss = 2 030 × 1·06 = 2 150.

And the probable full-load temperature-rise of the rotor (by Equation 5) is

$$\frac{2\,150}{4\,510} \times 35 \text{ deg. C.} = 16 \cdot 5 \text{ deg. C. (approx.)}$$

Probable full-load temperature-rise of stator by Equation (2), where V is assumed to be unity, is

$$36\left[\frac{2\,710 + 2\,720}{(4\,510 - 2\,150) + 2\,720}\right] = 38 \cdot 5 \text{ deg. C.}$$

The results of similar observations which were made on other machines are given in the table on page 1016.

VARIATIONS OF THE METHOD OF CONDUCTING THE TEST.

There are two principal deviations from the manner of carrying out the test on the lines previously described, and these are applicable to special cases, the main principles of reversed rotation and short-circuited secondary being adhered to in each case.

(1) A motor fitted with slip-rings capable of carrying the full-load rotor current continuously may be tested with its stator windings short-circuited and with a suitable supply voltage applied to the rotor. Normally the supply would be connected to the stator when the motor is in service, but if the test is arranged in this special way the stator windings carry the double-frequency current and the rotor current is at normal line frequency. This is particularly valuable for minimizing the losses due to eddy currents if the rotor bars are of heavy section and the stator windings of comparatively small section copper. The rotor current should be adjusted to a value corresponding to full-load current in the stator, where the full-load copper loss is to be produced. (It is presumed that the copper is small enough to allow the eddy-current loss at twice the normal frequency to be neglected.) In the rotor the current exceeds the value it would have at full load when the motor runs with the supply on the stator, and the extra rotor loss from this source and that loss contingent on the rotor frequency may be estimated on the lines already laid down. Hence the temperature-rise under these conditions on both stator and rotor windings affords a good indication of what may be expected on load if interpreted in accordance with the previous argument.

(2) It is sometimes found inadvisable to subject the rotor or the stator to currents which have a frequency double that of the line, owing to the prohibitive eddy-current losses which would result. The test on such a machine may be carried out by applying a supply voltage of half the normal frequency to the primary, still maintaining the normal speed of the rotor in the reverse direction. If f_1 = the normal frequency, the applied frequency is $\frac{1}{2}f_1$, and, since the rotor is running at nearly double the synchronous speed relative to $\frac{1}{2}f_1$ but in a reverse direction, the frequency of the secondary current is

$$\frac{f_1}{2} + \frac{2f_1}{2} = \frac{3}{2}f_1$$

which will help to keep down the eddy-current losses and, incidentally, the iron losses due to stray flux.

THE REGULATION OF THE EARTH POTENTIALS OF ALTERNATING-CURRENT SYSTEMS.*

By T. R. WARREN, B.Sc.(Eng.), Student.

(*Paper first received 5th January, and in final form 20th March*, 1925.)

SUMMARY.

The determination of the change in the value of the earth potential of any part of an alternating-current system, when that part is earthed through an impedance of known value, is one of the primary aims of this paper. The author has already investigated the problem for systems in which the earth capacity currents can be safely neglected,† but, since this condition does not always hold even approximately in practice, it is hoped that the complete solution of the problem will prove more useful.

The first part of the paper is devoted to the derivation of a simple equivalent network which represents the various leakage paths of the system, the method of solution being based on Kirchhoff's Law. The completeness of the theory in regard to its application under normal conditions of working is then demonstrated, and the effects due both to the presence of harmonics in the E.M.F. waves and to the voltage-drop along the mains are fully considered.

Following this there is a short description of methods to determine the values of F and K without interrupting the supply to the consumers. Formulæ are given which enable the separate values of f_1, f_2 and f_3 to be obtained in the case of three-wire three-phase systems.

The last section contains a discussion of the Petersen coil method of earthing, special reference being made to transient current phenomena. The dangers attending the use of the coil are explained, and it is pointed out that this method of earthing would be expected to fulfil the same duties on any type of alternating-current system, irrespective of the form of its voltage diagram.

INTRODUCTION.

It is now more than 20 years since experimental methods of determining the insulation resistance of direct-current systems under normal working conditions were first introduced, and in connection with these it will be sufficient to mention the names of Dr. A. Russell and Mr. F. C. Raphael. Dr. Russell also showed how the decrease in the earth potential of any main when connected to earth through a resistance of known value can be predetermined, provided the value of the insulation resistance of the system is known. This work has since proved to be of the greatest value to engineers both in the maintenance of supply mains and in the calculation of earthing resistances.

The need for dealing with alternating-current systems along the same lines soon arose with the advent of the more economical type of transmission, but, owing to the presence of the capacity effect between the mains and earth, it did not appear that the complete solution of the problem would, if obtainable, prove simple enough for ordinary practical purposes. It will be seen, however, that there is a distinct parallel between the alternating-current and the direct-current cases, the latter being merely a particular case of the former. This statement will become perfectly clear if we first examine the formula which gives us the insulation resistance F in terms of V, the earth potential of one of the mains, and V', the new potential when this main has been connected to earth through a known resistance x; for we have

$$F = \frac{V - V'}{V'} x$$

and the value of V' in this expression is clearly consistent with the value of the E.M.F. across a resistance x which is itself in series with a resistance F, the whole circuit being supplied with an electromotive force V. The existence of the equivalent network in the d.c. case at once leads us to suppose that a similar network possibly exists in the case of a.c. systems. It will be made abundantly clear in what follows later that this is indeed the case.

In arriving at the above formula it has been usual to assume that (1) all the leakage paths are located in the mains, and (2) each main is at the same potential throughout its length. Now, strictly speaking, neither of these assumptions is always realized in practice and, moreover, neither of them is actually necessary in proving the theory. Thus, instead of considering finite portions of the systems which are supposed to be at the same potential, we shall consider a given point and investigate the leakage current from it. The voltage diagram provides us with a convenient method of illustrating the problem, since actual points on the system can be represented by means of corresponding points on the diagram.

DERIVATION OF THE EQUIVALENT NETWORK.

In order to avoid the possibility of confusion arising over the use of certain terms, it is necessary to define what is meant by "insulation resistance" and "earth leakage capacity." By these we mean the resistance and capacity respectively between the various parts of the system and earth. These terms, therefore, do not take into account the leakage paths between the various parts of the system itself, because any currents flowing through these are merely in the nature of an ordinary load, and, since they do not flow to earth,

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

MARX: "Locating Earth Potential in Three-phase Installations and Measuring Insulation Resistance of High-tension Installations during Service," *Elektrotechnische Zeitschrift*, 1922, vol. 43, p. 1409.

they do not in any way affect the values of the earth potentials.

We shall first consider the case of a polyphase system in which the potential waves are sine-shaped, so that all the alternating quantities considered may be represented by means of systems of co-planar vectors. The more general case in which harmonics are present will be dealt with afterwards by means of the method of superposition. In Fig. 1 let PQ be any axis fixed with reference to the voltage diagram of the system, and let O be the point of zero potential. Since O is free to move in a plane, its position is expressed as a function of two independent variables, and two equations will therefore be necessary to locate it; these equations are deduced from Kirchhoff's Law.

If A is any point of the system whose earth potential is represented by the vector OA making an angle θ

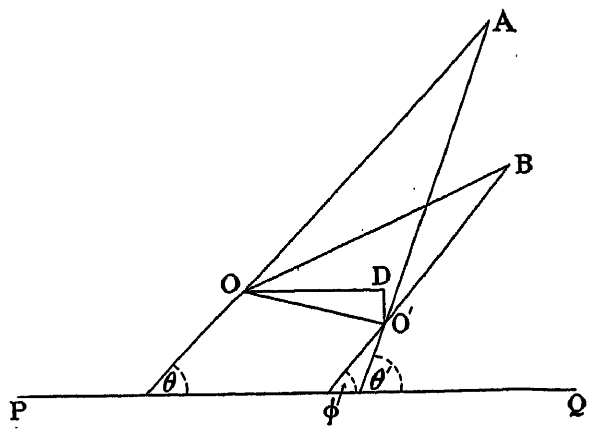

FIG. 1.—Vector diagram showing effect of earthing at B.

with the fixed axis, the leakage current C_A at A will be given by

$$C_A = \mathrm{OA}\sqrt{\left\{\left(\frac{1}{f_A}\right)^2 + (\omega k_A)^2\right\}}$$

where f_A = the insulation resistance at A,
k_A = the earth leakage capacity at A, and
$\omega = 2\pi \times$ frequency.

Also by Kirchhoff's Law we have

$$\Sigma C = 0$$

the symbol Σ denoting a vector sum. Therefore by resolving all the components of the leakage currents in directions parallel and perpendicular to the fixed axis we obtain, as the two equations determining the position of O,

$$\Sigma\frac{\mathrm{AO}}{f_A}\cos\theta + \Sigma\mathrm{AO}\omega k_A\cos\left(\theta+\frac{\pi}{2}\right) = 0$$

and $$\Sigma\frac{\mathrm{AO}}{f_A}\sin\theta + \Sigma\mathrm{AO}\omega k_A\sin\left(\theta+\frac{\pi}{2}\right) = 0$$

These may be written

$$\Sigma\frac{\mathrm{AO}}{f_A}\cos\theta - \Sigma\mathrm{AO}\omega k_A\sin\theta = 0 \quad . \quad . \quad . \quad (1)$$

$$\Sigma\frac{\mathrm{AO}}{f_A}\sin\theta + \Sigma\mathrm{AO}\omega k_A\cos\theta = 0 \quad . \quad . \quad . \quad (2)$$

If we now earth any point B (say) through a resistance x and a reactance r, then O will take up some new position O′, and (1) and (2) become

$$\Sigma\frac{\mathrm{AO}'}{f_A}\cos\theta' - \Sigma\mathrm{AO}'\omega k_A\sin\theta' + \frac{\mathrm{BO}'}{x}\cos\phi + \frac{\mathrm{BO}'}{r}\sin\phi = 0 \quad . \quad (3)$$

$$\Sigma\frac{\mathrm{AO}'}{f_A}\sin\theta' + \Sigma\mathrm{AO}'\omega k_A\cos\theta' + \frac{\mathrm{BO}'}{x}\sin\phi - \frac{\mathrm{BO}'}{r}\cos\phi = 0 \quad . \quad (4)$$

where θ' is the new value of θ, and ϕ is the angle made by BO′ with the fixed axis.

In the two preceding equations r is assumed to be inductive, but the alternative case in which it takes a leading current is easily taken into account by changing the signs of the terms in question.

By subtracting (1) from (3) and (2) from (4) we have

$$\Sigma\frac{\mathrm{OD}}{f_A} - \Sigma\mathrm{O'D}\omega k_A + \frac{\mathrm{BO}'}{x}\cos\phi + \frac{\mathrm{BO}'}{r}\sin\phi = 0$$

$$\Sigma\frac{\mathrm{O'D}}{f_A} + \Sigma\mathrm{OD}\omega k_A + \frac{\mathrm{BO}'}{x}\sin\phi - \frac{\mathrm{BO}'}{r}\cos\phi = 0$$

where D is the point of intersection of the parallel to the axis through O and the perpendicular to the axis through O′ (Fig. 1).

Since OD and O′D are constants, these equations may be written

$$\frac{\mathrm{OD}}{F} - \mathrm{O'D}\omega K + \frac{\mathrm{BO}'}{x}\cos\phi + \frac{\mathrm{BO}'}{r}\sin\phi = 0 \quad . \quad (5)$$

$$\frac{\mathrm{O'D}}{F} + \mathrm{OD}\omega K + \frac{\mathrm{BO}'}{x}\sin\phi - \frac{\mathrm{BO}'}{r}\cos\phi = 0 \quad . \quad (6)$$

Let us next replace all the leakage paths of the system by a resistance F and a condenser of capacity K at O, and suppose that the point of zero potential is now at some new point O″, while D is at some new point D′. Then by resolving the currents as before we get

$$\frac{\mathrm{OD}'}{F} - \mathrm{O''D'}\omega K + \frac{\mathrm{BO}''}{x}\cos\phi' + \frac{\mathrm{BO}''}{r}\sin\phi' = 0$$

$$\frac{\mathrm{O''D'}}{F} + \mathrm{OD'}\omega K + \frac{\mathrm{BO}''}{x}\sin\phi' - \frac{\mathrm{BO}''}{r}\cos\phi' = 0$$

where ϕ' is the new value of ϕ.

These equations are clearly similar in form to Equations (5) and (6) and, as in the previous case, they are each functions of the two variables which determine the position of O″. This being so, it is clear that the positions of O′ and O″ are each determined as the same function of the quantities F, K, x and r, and consequently these two points must coincide. This leads us at once to the important conclusion that the potential of any part of the system is regulated as though all the leakage paths are concentrated at a point of zero potential. The meaning of this is conveniently illustrated by means of the equivalent network shown

in Fig. 2, in which F and K in parallel are in series with x and r in parallel; the E.M.F. applied to the network is the original potential of the part of the system earthed, whilst the E.M.F. across x and r is the same as in the actual case.

In obtaining this result it has been assumed that the shape of the voltage diagram has not altered during the test, apart, of course, from the shifting of the point of zero potential. This assumption is perfectly admissible, provided that the load remains approximately constant, and also that the current through the artificial leak is not large, as otherwise there will be distortion due to voltage-drop. It is easy to see that the latter consideration interferes with the investigation of cases where heavy fault currents occur, since a correction now has to be applied which depends upon the constants of the system.

Before proceeding to investigate the applications of the theorem, it is important to determine the effects due to the presence of harmonics in the E.M.F. waves and to see whether the theory has to be modified in any way. The answer to this is readily seen if we consider each harmonic to exist separately; the equivalent network obtained in each case is the same, since the values of F, K, x and r are independent of the frequency. Thus, by superposing on one network the various harmonic components of electromotive force, the resulting current will be identical with the actual current flowing through the artificial leak.

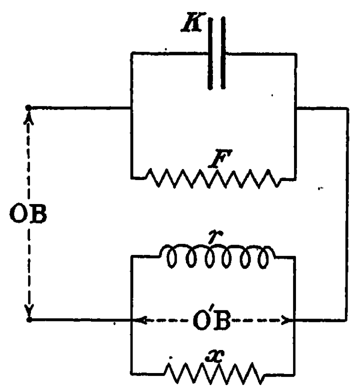

FIG. 2.—Diagram illustrating the equivalent network.

Practical Applications.

One of the most important questions with which station engineers have to deal is the interruption of supply due to faults. In the case of high-tension systems, experience shows that faults frequently occur on mains which are apparently sound, and thus we have no means of predicting their occurrence. In low-tension systems, however, faults are usually preceded by a gradual deterioration of the insulation of the faulty section, thus giving warning of the approach of a breakdown. The importance of being able to keep a continuous record of F can, therefore, hardly be over-estimated, since a sudden decrease in its value may always be taken to herald the approach of trouble, whatever the type of system may be.

It may be mentioned that cables embodying "test sheaths" are being received with increasing favour by the electrical engineering industry, since these enable the insulation resistance of that part of the cable exterior to the sheath to be found separately for each feeder. In this way the faulty sections are immediately located, and, where possible, repairs are executed.

The importance of knowing the value of K is, in general, less than that of knowing F, but exceptions occur in cases of systems earthed through inductances. In particular we might take the case of the Petersen coil which is more fully considered in the last section. With this type of earthing, the effect of the capacity is neutralized by the inductance of the coil which is tuned to resonance with it at the fundamental frequency. Knowing K, therefore, the value of the inductance required is also known, and the coil can then be designed accordingly.

Another important class of problem which calls for solution is the following. Suppose we wish to reduce the potential of any part of a system to a given value. What earthing resistance will have to be connected to this part in order to effect this? The answer to a problem of this type is easily calculated from the equivalent network, provided we have previously found F and K, methods of doing which will now be suggested.

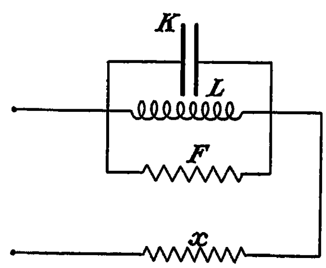

FIG. 3.—Diagram showing how the capacity effect in a system is neutralized by means of an inductance.

Determination of F and K.

The method of procedure which appears to be the most convenient from a practical point of view is as follows. Connect a variable inductance between any convenient part of the system which is at a low potential and earth, at the same time noting the voltage across it by means of an electrostatic voltmeter. When the reading on the meter reaches a maximum value for a given value L of the inductance, then K may be found from the formula

$$K = \frac{1}{\omega^2 L} \qquad (7)$$

This relationship is only strictly true when no harmonics are present, but, in cases where a serious error may be introduced by making such an assumption, resonance with one of the harmonics can easily be obtained by means of an oscillograph, and the value of K can then be found.

If the inductance is retained in position, the system now virtually possesses fault resistance only, as is easily seen by the equivalent network (Fig. 3) which

represents this new condition. It follows at once that F may be found by connecting a known resistance x between any part of the system and earth, and then, by noting the potential V before the connection is made and its new value V' afterwards, we get

$$F = \frac{V - V'}{V'}x \quad . \quad . \quad . \quad . \quad . \quad (8)$$

An easy way of obtaining the total fault impedance is to observe the potential V'' (say) of any part of the system and the current I which flows through an ammeter connecting this part direct to earth. We then find

$$\frac{I}{V''} = \sqrt{\left\{\left(\frac{1}{F}\right)^2 + (\omega K)^2\right\}}. \quad . \quad . \quad (9)$$

By the use of this formula we need not know the value of L in (7), since K may be found from (8) and (9) to be given by

$$\omega K = \sqrt{\left[\left(\frac{I}{V''}\right)^2 - \left\{\frac{V'}{x(V - V')}\right\}^2\right]} \quad . \quad (10)$$

This formula, however, will not give reliable results when ωK is small compared with $1/F$, since small percentage errors in the meter readings may introduce in this particular case a large error in the value of K. Generally speaking, therefore, it will be better to use a calibrated inductance and so be able to read the value of L.

We may take as an example a system having a frequency of 50 cycles per second. If L is $0 \cdot 5$ henry, then

$$K = \frac{10^6}{(2\pi)^2 \times (50)^2 \times 0 \cdot 5}\mu\text{F} = 20 \cdot 5 \ \mu\text{F (approx.)}.$$

If we now earth through a resistance of 50 ohms, thereby reducing the potential from 60 volts (say) to 11 volts, we find from (8) that

$$F = 50\left(\frac{60}{11} - 1\right) \text{ ohms} = 222 \cdot 7 \text{ ohms (approx.)}.$$

The reciprocal of the total fault impedance is, therefore,

$$\sqrt{\left\{\frac{1}{F^2} + (\omega K)^2\right\}}$$
$$= \sqrt{\left\{\left(\frac{1}{222 \cdot 7}\right)^2 + (100\pi)^2 \times (20 \cdot 5)^2 \times 10^{-12}\right\}}$$
$$= 0 \cdot 0078 \text{ (approx.)}.$$

If, therefore, we wish to apply formula (10), we should find that the current flowing through a dead earth at a point originally at potential 100 volts would be $100 \times 0 \cdot 0078$ ampere, or $0 \cdot 78$ ampere. By observing this ammeter reading we may deduce the total impedance when L is not known, and by the application of formula (10) we find

$$\omega K = \sqrt{\left[\left(\frac{0 \cdot 78}{100}\right)^2 - \left\{\frac{11}{50(60 - 11)}\right\}^2\right]}$$
$$= 6\,430 \times 10^{-6}.$$

from which $K = 20 \cdot 5 \ \mu\text{F}$ as before.

It is an interesting fact that the power consumed in the resistance x in formula (8) reaches its maximum value when $x = F$. It is unfortunate, however, that in most of the cases met with in practice this power is too small to be measured conveniently by a wattmeter, for otherwise we should be furnished with a convenient method of measuring F directly from a calibrated resistance.

In order to keep a watch upon the state of the insulation resistance of three-phase systems, electrostatic voltmeters are sometimes connected between the mains and earth, a low reading on one of the meters being taken to indicate that a fault is developing in the main to which this particular meter is connected. The objection to this method is that it does not show whether all the mains are deteriorating at the same time, and from this point of view it is perhaps better to use mains constructed with test-sheaths. The following method of determining the insulation resistance of each of the three mains separately, assuming that all the leakage paths are located in the mains, may be applied to low-tension systems.

The first step is to earth through an inductance so as to neutralize the capacity effect as previously explained. Let V_1, V_2 and V_3 be the resulting potentials of the three mains, while V denotes the line voltage. Now earth the main having the potential V_3—choosing it so that it is greater than V_1—through such a resistance x (say) that the new potentials V_1' and V_3' are equal. Then the author has shown * that the required resistances f_1, f_2 and f_3 are given by the following formulæ :—

$$f_1 = \frac{\sqrt{3}VFx}{V_2'(F + x)}$$
$$f_2 = \frac{\sqrt{3}VFx}{(\sqrt{3}V - 2V_2')(F + x)}$$
$$f_3 = \frac{\sqrt{3}VFx}{V_2'(F + x) - \sqrt{3}VF}$$

where V_2' is the new value of V_2 and

$$\frac{1}{F} = \frac{1}{f_1} + \frac{1}{f_2} + \frac{1}{f_3}$$

But we already know that

$$F = x\left(\frac{V_3}{V_3'} - 1\right)$$

and by substituting this value of F in the above formulæ we have finally

$$f_1 = \frac{\sqrt{3}V(V_3 - V_3')x}{V_2'V_3}$$
$$f_2 = \frac{\sqrt{3}V(V_3 - V_3')x}{(\sqrt{3}V - 2V_2')V_3}$$
$$f_3 = \frac{\sqrt{3}V(V_3 - V_3')x}{V_2'V_3 - \sqrt{3}V(V_3 - V_3')}$$

* *Loc. cit.*

THE PETERSEN COIL.

The method of earthing systems by means of inductances is one which has received more favour abroad than in this country, so a few remarks on this subject given in the light of the present theory will no doubt be of interest to a great many of those who study Continental practice.

The particular value of earthing inductance which produces resonance with the capacities of the cables constitutes the well-known Petersen coil. It is clear from what has been said before that under normal conditions the coil will have the effect of raising the potential of the main to which it is connected by an amount which is limited by the value of F, and that unless this value is determined under the most favourable conditions, i.e. in dry weather and during light load, we are relying for safety upon an unknown factor —a policy which, though not to be commended, is often pursued.

Another apparent source of danger lies in the possible increase of the "residual" voltage of three-phase systems due to possible unbalancing of the insulation resistance of the mains such as might occur when a consumer switches on a piece of apparatus which is slightly faulty. This appears to account for the failure of some systems to give good results with this type of earthing. With overhead transmission lines it is usual to balance the capacities of the mains as far as possible by transposing the wires at regular intervals; in this way the risk of breakdown is reduced to a minimum.

Under fault conditions the fundamental-frequency current flowing through the fault is merely that due to the faulty insulation of the rest of the system, and, in the case of a dead earth, is obtained by dividing the original potential of the faulty part by F; in general, this current is negligibly small. It is found that this diminution of fault current is accompanied by an almost complete suppression of the troublesome high-frequency oscillations which are usually produced in high-tension systems under fault conditions. Several suggestions have already been advanced as to why the "Petersen coil" method of earthing is so much superior in this respect to the resistance method.

One explanation at least may be obtained from the equivalent network, because a little consideration will be enough to convince us that there is no tendency for transient currents to flow through the fault at all, since there is no inductance in series with K. On the other hand, if the coil were replaced by a resistance so that the fault current is considerably increased, the effect would be to alter appreciably the potential of every part of the system owing to the voltage-drop along the mains and in the generator and transformer windings. It will be recalled that the theory given above does not take this case into account, but the effect of thus distorting the voltage diagram will be easily understood. For example, if the effect is to change the potential of some point A, while the potential of another point B is changed to the original potential of A, then the fault impedance at A appears to be in series with the impedance of the section AB. From this it would appear that the capacity K is, in this case, virtually in series with an inductance which depends upon the line constants, and in this way we can account for the presence of the familiar transient currents.

Since, as we have seen, the theory which has been investigated does not depend in any way upon the type of distribution employed, it follows that the Petersen coil can be used with equal success in connection with any type of a.c. system, irrespective of phase. This property of the coil is perhaps of little value at present in these days of three-phase transmission, but multiphase transmission at 110 000 volts has already been suggested as a possibility for the future, and the problem of eliminating interference with telephone circuits will then perhaps call for a revision of the methods of earthing at present employed.

DISCUSSION ON

"THE DESIGN OF ELECTRICAL PLANT, CONTROL GEAR AND CONNECTIONS FOR PROTECTION AGAINST SHOCK, FIRE AND FAULTS."*

North-Eastern Centre, at Newcastle, 23 February, 1925.

Mr. R. W. Gregory: The high standard of service required from the electric supply undertakings in this country, and the high standard of safety required to meet the various Government Regulations in connection with the supply and use of electricity, are perhaps the primary reasons for metal-clad switchgear. The electric supply undertakings in England have never had the pioneering freedom which is the outstanding feature of electrical development in the United States. For this reason, instead of developing a general system of high-tension overhead distribution and workmen not afraid of high voltage, we have in this country developed the arts of making underground cables and metal-clad switchgear. Development on these lines has probably cost us more per unit sold, but at least we have had the satisfaction of approaching perfection in the practice of these arts. Within the limits of the distribution pressures common in Great Britain, iron-clad switchgear has proved to be sound engineering. The compact, fully interlocked, factory-assembled switch-panel is an excellent engineering job, giving what might be termed the "Rolls Royce" service generally expected by the British consumer. The world-wide researches on oil circuit-breakers do not yet appear to have provided data for direct design, such as is possible with the steam engine or gas engine, but they have, together with increased experience in service, added greatly to the general knowledge of circuit-breaker design, and buyers in this country have now a wide market in which to obtain good circuit breakers capable of giving efficient service. The commercial and economical use of the science of breaking capacity is an interesting problem. In practice, on a soundly designed system using underground cables and metal-clad switchgear, the maximum fault is a very rare occurrence, and in many places it is often technically and commercially sound to use switchgear rated at less than the maximum fault kVA. Where this course is followed, it is necessary to make sure that the operator is not exposed to danger when closing a switch on a fault. For this reason, remote operation is desirable. With regard to power station switchgear, it is interesting to compare the development in this country with that in America. The switchgear in the Carville "B" power station of the Newcastle Electric Supply Co. was erected about the same time as the switchgear for the Calumet station in Chicago. The problems to be solved in both stations were practically the same, but the method of solving was entirely different. It was realized by both parties that it was essential to do the utmost to prevent a fault between phases. The Carville method of meeting this point was to build a strong compact gear in which earthed metal everywhere surrounded each phase. The Calumet method was to provide an entirely separate room for all the apparatus and conductors belonging to each phase. The differences in dimensions and appearance between the two types of gear are considerable. It shows how marked is the difference between the two countries in switchgear engineering practice. One of the most important problems in high-tension switching is the provision of cheap apparatus suitable for using on large power systems, and at the same time meeting the stringent requirements of operating staffs and Government Regulations. Cheapness is best obtained by reducing the amount of apparatus used and by making that which remains the best possible. The switch-fuse described by the author, and the single-switch substation, are attempts to reduce the cost of switchgear necessary for a high-tension supply and at the same time to give the service and safety necessary for British conditions. The author has not mentioned in his paper the question of switchgear control. Centralized control of system switching is now considered to be essential practice on large power networks, and the control engineer (or load despatcher) should know as quickly as possible whenever and wherever a switch has operated. There are now on the market several types of apparatus which, by the use of telephone cables, are able to perform this function. The next step, which I am sure will be generally adopted before many years elapse, is the actual physical control and operation of important switches on the system from the central control room. With automatic indication and supervisory control, the maintenance of service will be made easier and more secure and shut-downs over large areas, if not entirely prevented, will at least be of the shortest possible duration.

Mr. F. H. Williams: According to the author, the essentials of good switchgear practice are "simplicity" and "security," and no one who has to deal with large power schemes will fail to agree with this. Design of such switchgear is really a matter of faith and ideals. The author believed that he could design and manufacture, as a commercial article, switchgear which could stand up to any conditions likely to arise in practice, and events have justified this confidence. Other manufacturers, particularly on the Continent and in America, apparently not having the same faith in their products, have thought it necessary to introduce various additional devices to reduce the short-circuit forces. These devices, in addition to requiring extra maintenance, sometimes introduce further complications and, in the very nature of things, must be an additional source of weakness. The charging resistance mounted on the cross arm referred to in the paper is one such device, and is standard practice for all high-tension switches with one of the

* Paper by Mr. H. W. Clothier (see page 425).

biggest switchgear makers on the Continent. This manufacturer also uses the multiple-break system referred to by the author, increasing the number of breaks with the kilovolts of the circuit. One would have thought it an obvious source of weakness to mount this resistance on the cross arm. It cannot be too strongly emphasized that the simpler the switchgear, other things being equal, the better it is. I do not think the author claims sufficient credit for the compactness of the ironclad gear, and it would have been instructive to have, as an appendix, the comparative total cost (including buildings) of a switch-house for metal-clad gear and open-type gear based on the same kVA rating. It is difficult, for instance, for anyone unacquainted with metal-clad gear to realize that the unit shown in Fig. 7 houses, in a total height of under 10 ft., gear which in cellular construction, with about the same floor-space, would have to be accommodated on three or four floors, with a total height of 30 to 40 ft. The saving in buildings is really most striking, quite apart from the advantages of cheaper maintenance and greater security. If one may venture to criticize the paper, I would suggest that its value for reference purposes would be increased if the footnotes were amplified. I should also like to ask the author for further particulars of the semi-fluid insulating compound referred to on page 429. I have not come across this and, offhand, it does not sound very inviting.

Mr. N. Thornton: The principle of metal-clad switchgear is undeniably sound and affords many advantages, the chief among which are: the extreme compactness of the gear, so requiring only a small building in which to house it, and that without any cubicle structure, screenwork or other special forms of guarding; the ease with which it lends itself to any desired scheme of interlocking; and the fact that cleaning and maintenance are reduced to a minimum. It has, however, one drawback, in that it increases the length of a shut-down when it is necessary to make additional connections to the busbars, a point which is of some importance when considered in relation to the supply to domestic networks. Unfortunately, too, it has generally been found that the initial cost of metal-clad switchgear was greater than that of open-type switchgear, but this has to a large extent been offset by the reduced cost of buildings. The increased adoption of metal-clad switchgear tends to indicate that the general opinion is beginning to appreciate that any such increased cost is warranted by the subsequent decreased cost of maintenance and repairs. The split-conductor system is referred to as being an exceptionally useful and economical form of protection, which is quite correct, but it must be borne in mind that this condition only obtains so long as the feeder is required as a direct connection between two points. Immediately it is desired to give intermediate supplies off that connector the situation is altered and this type of protection is no longer consistent with economy of switchgear. This is of particular importance where intermediate supplies may be required for domestic networks, in which case the capital cost is all-important. The cost of taking supply by means of a loop-in of the split-conductor feeder, and of providing two split-conductor feeder panels in addition to apparatus required to control the intermediate supply, would in many cases prove to be prohibitive.

Mr. J. Rosen: In Fig. 36 the author has shown an arrangement for bringing the alternator stator leads out at the side to a terminal box attached to the stator end shields. I do not entirely agree with this arrangement, as there is only a limited space available for such apparatus in the modern alternator end-shields. If a similar distance is allowed between each phase terminal, as is shown between the phase and earth terminals in the figure, the depth of the end shields will have to be increased. This, and other difficulties, would, I am afraid, render the proposal impracticable. The usual method is to bring the leads out under the end shields, as shown in Fig. 1; I prefer to use terminals bolted to the chimney of the stator casing, as it is advisable to have between the cables and the alternator windings a joint which can be readily broken should the alternator stator be lifted at any time. The author refers to the automatic arrangements for closing the ventilating system and shutting the steam stop-valves, in order to limit the possibility of a fire spreading inside an alternator. In this connection, the closed-circuit system of forced ventilation, in which a comparatively small quantity of air is circulating continuously, acts as a safeguard; if a fault occurs in the alternator the air system is filled with burnt gases and the fire is extinguished at once. Great care should be taken in the design of switchgear for turbo-alternator auxiliaries. Recently plants have been shut down due to the failure of auxiliary switchgear. This apparatus should be robust and have the number of accessories reduced to a minimum. The author refers to self-balanced protection. This is one of the most reliable devices which can be used to protect alternator stator windings. With reference to the sequence of control, I would emphasize the importance of the author's proposals, and take the opportunity of pointing out that the field switch without a discharge resistance should only be operated in an emergency and must not be operated when the main oil switch is tripped by hand for testing the switchgear. With the large amount of magnetic energy in the present-day large alternators when the field circuit is suddenly interrupted, high voltages are induced and heavy currents circulate which, if repeatedly applied, might in course of time damage the alternator.

Mr. B. H. Leeson (*communicated*): The author has very rightly described "Stability" as the "Criterion of Quality" of a protective system, and the expression of this as a numerical value is a very welcome step towards establishing a recognized method for the comparison of various protective systems. In furtherance of this desirable object I should welcome the author's opinion upon the following comments. I shall preface these by reference to Fig. D, which depicts in the form of a genealogical table, for clearness, the chief conditions and factors which have to be considered. This is self-explanatory and will help to illustrate the remarks that follow. The numerical value for stability ratio obtained by the author's method of dividing the maximum straight-through current by the fault setting will depend

solely upon the designer's or manufacturer's judgment regarding the minimum fault-current setting that can be safely adopted "without any risk of inadvertent tripping, after taking all the disturbing influences into consideration." Now it is just this degree of risk which has been taken, or, conversely, the margin of safety which has been allowed, that the operating engineer particularly wishes to know, and hence I think that any method of expressing stability should essentially give a definite measure of the manufacturer's conservatism, or otherwise, in the form of a safety factor. The fundamental conception of stability may be best expressed as the ratio of the minimum straight-through current in service which would be required to cause inadvertent operation of the protective gear, to the maximum straight-through current that can possibly flow in the system. This, however, is rather an impracticable method owing to the difficulty of obtaining tangible figures, particularly for the numerator, and further, this expression might lead an optimistic designer

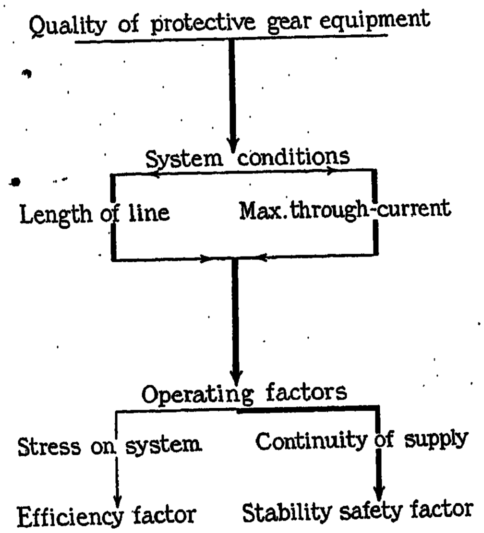

Fig. D.

to be tempted to make the numerator "infinity," thus falsely indicating infinite stability. I should therefore prefer to express stability in the form of a safety factor for a given straight-through current on the system as follows:—

$$\text{Stability safety factor} = \frac{\text{Service fault setting (actual)}}{\text{Minimum safe fault-current setting for stability, determined by tests (ideal)}}$$

In this expression the figure forming the denominator is obtained by an actual test carried out in such a manner as to reproduce as far as possible all the disturbing influences which will be met with in service for a given maximum value of straight-through current. The service fault setting is the actual value at which the relays will be set to operate in service, and the margin of safety above the test figure will allow for the hazards in service which cannot be faithfully reproduced artificially. By this means an operating engineer is given a definite idea of the margin of safety possessed by his protective system to ensure stability. The desirable value for this factor will depend upon the tactical importance of the protective gear on the system, but in any case I would suggest a minimum figure of 2, increasing this up to 4 in the more important cases. Following the author's lead in regard to stability, I think it would be desirable to introduce a term to show the relative efficiency of protective gears and I suggest the following expression:—

$$\text{Efficiency factor} = \frac{\text{Maximum straight-through current on the system (fault between phases)}}{\text{Service fault-current setting for given stability safety factor}}$$

This will give a numerical value to the efficiency of a protective gear after allowing a definite degree of stability, and the latter will guard against any false sense of security due to the rather natural appeal (at first sight) of low fault-current settings. The efficiency factor and the stability safety factor are naturally opposed to each other in principle. When judging the relative merits of these, primary consideration should be given to stability as the criterion of quality. It should be borne in mind that it is better to have lower efficiency and a reasonably heavy earth fault current to burn out and clear a fault immediately, than to have a higher efficiency with a light setting, risky stability, and then final resort to burning out the fault to determine its location. In addition to the stability of protective gear, "continuity of supply" depends primarily upon a high standard of insulation. It is a great pity that the rule for determining test-voltages in our B.E.S.A. Specification No. 116 should set a lower standard than that commonly used in the country from which it originated. The American manufacturers have virtually raised the standard by adopting, and applying the rule to, an arbitrary voltage rating for their switchgear which considerably exceeds the normal rated voltage of the system for which it is suitable. In view of this, the author's higher standard of pressure tests is to be strongly recommended. Since, however, insulation should not be judged entirely upon its ability to pass a high-pressure test successfully, it would seem desirable to follow along similar lines to the case of the protective gear and introduce a definite margin of safety to ensure that the test does not approach the ultimate breakdown point of the insulation too closely and thus perhaps tend to overstrain it. I suggest that this margin may also be expressed in the form of a safety factor as follows:—

$$\underset{\text{(for a given time)}}{\text{Insulation safety factor}} = \frac{\text{Minimum voltage at which ultimate breakdown occurs}}{\text{Specified test voltage}}$$

By specifying this factor of safety in conjunction with the test pressure, a purchaser would obtain a definite guarantee of insulation security with the knowledge and assurance that the insulation provided would not be liable to harmful over-stress during the test. The value of these safety factors is a matter for further research, but as a guide I would suggest that in cases

of puncture stress a figure of 2 should be taken as a minimum. I think it would be very helpful if the terms " efficiency factor," " stability safety factor " and " insulation safety factor " could receive the consideration of the B.E.S.A. with a view to introducing some form of standardization upon the lines indicated above.

Mr. L. E. Mold (*communicated*): The author has illustrated various methods which may be employed in transferring a circuit from one set of busbars to another either with or without interrupting the supply to that circuit. This operation has probably caused more interruptions to supply and accidents to operators than any normal routine duty in a power station. Admittedly, the accidents of which I have knowledge have occurred when operating open knife-type selector switches, and the methods recommended by the author eliminate this risk, but some of the designs illustrated introduce other serious dangers and risks. In Fig. 9 the operator is required to remove and insert plugs which engage with the busbars. The insulation on a loose piece of apparatus like a detached plug with an insulating handle is liable to damage, with consequent likelihood of a fatal shock to the operator. The removal of a plug whilst carrying current appears to be possible in certain conditions, and the resultant arc would be equally dangerous to the operator and to the switchgear. In Fig. 11 the change-over can be effected with reasonable safety, but the design entirely destroys the feature of safety usually associated with a duplicate busbar system. Connections from both busbars are brought into a common circuit-breaker tank, and it is reasonable to admit the possibility of failure due to an arc or its products in breaking a heavy fault current. Even under normal conditions with both busbars alive and unparalleled the voltage stresses may be doubled. Fig. 12 is safe in operation, since sound interlocks can be fitted, but it partly suffers from the disadvantage of the arrangement shown in Fig. 11, in that connections from both busbars are brought into one chamber although circuit-breaking does not take place in this chamber. Fig. 10 illustrates a very sound arrangement. If one circuit breaker only is employed the circuit must be broken to effect a change-over and if, in order to obviate this, two are employed the cost is greatly increased in the unnecessary duplication of parts. Fig. 8 is simple and effective, affords perfect safety to the operator, and ensures that the circuit is broken only in the circuit breaker; it is necessary, however, to open the circuit breaker to effect the change-over. My object in alluding to these features is an endeavour to ascertain whether the necessity really arises for the transference of a circuit from one busbar to the other without opening the circuit. The author advances sound arguments against this procedure (see pages 429 and 430). My own experience, and the result of many inquiries from station engineers, indicate that this function is more fanciful than necessary. The author has given four reasons justifying the necessity of a duplicate busbar, and these reasons consequently cover the necessity of changing circuits from one busbar to the other. A fifth may be added where certain feeders are required to operate at a different pressure, but the more convenient and economical method is to provide voltage regulators on the feeders. This leaves two conditions (1 and 2 on page 428). The first is of doubtful value and the second is nearly always met by the normal provision of busbar section switches which will enable all circuits from one section to be opened for a minute or so to effect the change-over. A reliable expression of opinion on this question would be of very great value.

[The author's reply to this discussion will be found on page 1031.]

East Midland Sub-Centre, at Loughborough, 10 March, 1925.

Mr. T. P. Wilmshurst: I quite agree with the author as to the advantages of metal-clad gear in eliminating danger and cleaning. One point is that there is no possibility of inspection where the apparatus is iron-clad. Is there not more difficulty in locating any fault which may develop? As our stations grow we have from time to time to consider the necessity of enlarging the sectional area of busbars, but with metal-clad gear it is impossible to do this. We have to deal with systems which have started from small beginnings, and with open-type cellular gear it is possible to make additions from time to time if necessity arises. An important point is that with cellular gear the conductors form their own diagram and a fault can be quickly located and easily put right. I should like to ask what is the correct protection for a unit transformer. Should there be any automatic protection between the stator terminals and the e.h.t. terminals of the transformer? With regard to overhead protection in rural districts where expensive switches cannot be afforded, has the author any experience with the tetra-chloride type of fuse and will he also say what type of fuse is used in the out-door substation shown in Fig. 27? Is there any danger to be anticipated due to the corona inside metal-clad gear tending to break down the insulation?

Mr. J. F. Driver: The author referred to the Rayworth pillar: this was an excellent type of switchgear, but the water switch gave trouble. One form of danger not mentioned in the paper, but which is serious, is a flash occurring close to an operator. This sometimes causes acute agony to the eyes. I am rather surprised that oil should be used in transformer junctions as a suitable insulating medium. In one case which came to my notice of an explosion due to an oil-filled junction box, what apparently happened was that the oil got hot due to a bad contact and boiled out, and possibly a small spark fired the gas and the transformer room blew up. I suggest that a material which would solidify would be better than oil. I do not understand the author's remarks with reference to lightning protection. I have not found lightning arresters very efficient on traction work. Has he seen definite signs that a lightning arrester has worked, i.e. has cleared a current-rush to

earth, particularly in a case where the discharge is supposed to dissipate its energy in the conductor itself?

Mr. T. Hall: Has the author had any experience with pole boxes? I have a system working at 11 000 volts and much trouble occurs with the type of pole box I am using, due to insulators breaking down. I have also had trouble on switchgear insulators, due to a static discharge, and I should be glad if the author would indicate the best way of getting rid of this.

Mr. H. V. Field: The introduction of reactance apparently does not limit the short-circuit power and protect the switches to the extent that would be expected, owing to the fact that the arc energy does not decrease in the same measure. Can the author suggest why that is the case? In regard to the curve given on page 430 for busbar current densities, what is the actual temperature-rise? The method employed for obtaining condenser protection against lightning and high-frequency transients by using half a mile of cable before joining up with the overhead line is very interesting. Has any trouble been experienced at the joint between the cable and the overhead line? With regard to Merz-Price balanced protective gear, Figs. 32 and 33 indicate great complexity and one wonders how such complex systems have come into use. Protective gear seems to be getting more complex than ever, instead of tending towards simplicity. In Fig. 20 the area for getting rid of gases and fumes seems to be a very good idea, but if the generators are laid out as shown this would not be a very good design of power house. One of the lantern slides exhibited showed a switchroom in which upward isolation was used, but it appears to me to be a very unsatisfactory layout. I should imagine that vertically downward isolation would have been much more satisfactory in that case.

[The author's reply to this discussion will be found on page 1031.]

NORTH MIDLAND CENTRE, AT LEEDS, 24 MARCH, 1925.

Mr. W. Howard Brown: I agree with the author that the time has come when we should cease to stress the advisability of purchasing duplicate switchgear, at any rate for ordinary industrial use; there is no more need to duplicate busbars than there is to duplicate main engines or turbines. It is now relatively easy to provide a.c. protection, but I should like the author to give us his views on the protection of d.c. plant, especially in regard to the sequence operation of circuit breakers and similar apparatus. I should also like his opinion as to the advisability of using resistance in series with fuses on the h.t. side of potential transformers. How far does he consider this practice can profitably be carried out in respect of comparatively small-power high-tension feeder circuits? It is interesting to note that the author throws some doubt on the advisability of adhering strictly to the B.E.S.A. specification for oil switches and suggests that alterations might very well be made. Many engineers, I think, will agree with him in this. I should be glad if he would give the result of his experience with lightning arresters as used on the North-East Coast undertaking.

Mr. J. W. J. Townley: I consider that under the conditions which obtain in this country armour-clad switchgear is the most suitable, and I venture the opinion, based on my experience with both open-type and armour-clad gear, that there will be very little open-type switchgear in use in 10 years' time. The serious defect of open-type or cellular switchgear is that once an arc is started a considerable number of panels can be put out of commission in a very few minutes, and with very little damage being done except to insulators and small connections which take a long time to replace. I know of one case in which an arc was started, due to the faulty operation of an oil switch, travelled up to and along the busbars and put seven panels out of commission by breaking busbar insulators; the capacity of the plant running was only 2 500 kVA. In another case an arc, started by the burning out of a current transformer on cellular open-type gear, destroyed five panels in 22 seconds. The capacity of the plant in this case was about 50 000 kVA. In each of the above cases the conductors were bare and the phases separated by slate or concrete barriers, which latter, however, had little effect in isolating the trouble. It is interesting to note that in modern cellular gear many designers are adopting the expedient of enclosing all conductors in insulated covering. Where the plant is of large capacity, on the occurrence of a fault the rupturing forces in metal-clad gear are likely to be of considerable magnitude, and extended experience in the behaviour of metal-clad gear under such conditions has yet to be gained. It must be admitted that the adaptability of such gear is not so great as that of open-type switchgear, but it is sometimes an advantage to know that extra-high-tension switchgear cannot be modified or added to excepting by the use of properly made details. The author advocates ruggedness in the design of protective gear, and this is one of the most essential points that station operators have to ensure. Protective gear has been installed in the past which has given much more trouble than the faults it is intended to guard against. Earthing resistances have been installed when plant capacities were small and have not been modified as the plant has been increased, and in many cases this results in the generating plant being almost entirely unprotected owing to the current passing the earthing resistance being insufficient to operate the relays. In view of the type of plant now being installed (turbo-generators) it is worth while considering whether the time has now come when the neutral point may be earthed solidly and without using expensive resistances. The question of interlocks on switchgear is not one for the decision of the switchgear manufacturers, who can usually supply any system of interlocking, but is one to be decided by the user. The arrangement shown by the author for changing over from busbar to busbar should meet all reasonable requirements in a power station, and I agree with him that such operations are relatively infrequent and should never be done

hurriedly. The author has given his opinion as to the breaking capacity required for any given size of plant, but has not suggested how we are to determine the breaking capacity of any particular oil switch excepting only on the basis of oil tank cubic content and strength. An amplification of the author's comments in this part of the paper would be appreciated.

Mr. R. M. Longman: Protective gear is blamed for much of the trouble that occurs, but in very many cases it is not given a chance, as it is connected up incorrectly. Has the author any experience of breakage or failure of a right-angle box in any of the positions shown on the lantern slides? With armour-clad gear the highest class of workmanship and material is absolutely necessary. Every manufacturer has, I think, fully realized that he cannot be too careful and particular in his inspection and examination. With regard to protection, it is sometimes asked what is the use of putting in relays and sensitive protective devices, when a fault might occur on a particular cable only once in five or ten years. The answer is, of course, that protection is not only to operate in the case of a fault but to prevent a sound section being cut out when the fault is beyond that particular section. I fully agree with the author on the question of the rating of switchgear, etc. It appears to me that the scheme shown in Fig. 28 has many advantages, one of which is the arrangement of the current transformers; nothing is left unprotected. In connection with the tee protection for the transformers, is any sort of overlapping arrangement provided so that should the fault on the transformer be rather more than the switch fuses could legitimately deal with, the section would come out?

Mr. S. D. Jones: It seems to me that the closed type of switchgear does make for greater efficiency. With regard to cleaning, much more of this is required with the open type than with the closed type. We are now connected up in parallel with the Yorkshire Electric Power Co.'s system. When I received tenders for the new switchgear connecting the two systems, I asked what the breaking capacity of the circuit breakers was, but could not obtain a satisfactory reply from the manufacturers.

Mr. W. D. Lovell: I am somewhat surprised that the author makes no reference to any type of closing device for use on direct-operated metal-clad gear, which can be temporarily attached to any switch mechanism, enabling the switch to be closed at a distance from the panel. In practice it often becomes necessary to switch-in doubtful apparatus, and the operator on these occasions runs a fair amount of risk unless some special form of closing device is available. One or two devices for this purpose have been developed and are being used successfully on some of the large power supply systems. The interlocking of duplicate busbars has caused a great deal of discussion for many years, and I fully agree with a previous speaker that it is more a matter for operating engineers than manufacturers to decide, as it depends largely on the design of each individual system. In view of the serious accidents that have occurred when changing-over circuits from one busbar to another while carrying load, I cannot help thinking that the opening of each circuit before the change-over is made, advocated by the author, is the correct method to adopt. The question of earthing has always been a very difficult problem on metal-clad gear, and although the arrangement shown in Fig. 24 appears to be a step in the right direction, there is still plenty of room for improvement. It would appear that before the arrangement suggested can be used on existing gear of some makes, it will be necessary to modify the shutters and oil-switch locking devices. On page 438 the author states: "If any mistake is made it will be no more serious than closing on a fault," and I should like to ask him whether this is quite correct. The earthing, unfortunately, is being done on the busbar side of the current transformers and outside the feeder protection, so that if by chance the feeder is alive, and assuming all three isolating plugs are short-circuited and connected to earth, the closing of the switch will produce a three-phase busbar fault. Should the feeder protection be of the balanced type it will be inoperative under these conditions and the fault will have to be cleared by the opening of the nearest sectionalizing switch, which on a ring system may be some considerable distance away. This may cause an interruption of supply over a large area. In connection with the "straight through" current rating, has the author carried out any experiments to determine the weakest link in the gear under these conditions? Referring to Fig. 3, will the author state what the disadvantages are in using three-core cable-dividing boxes in place of single-core sealing bells? In the former case, the three-core cable could be connected direct to the transformer, whereas the latter arrangement necessitates an additional dividing box. It is interesting to note that the author does not agree with the B.E.S.A. Specification No. 116 as regards breaking capacity, and I am sure that there are quite a number of operating engineers who are in agreement with him on this point. With reference to Fig. 37, showing the connections of self-balance protection for generators, I should be interested to know how the author proposes to protect the cables between the machine and switch. Presumably he would use Howard leakage protection.

Mr. D. M. Buist (*communicated*): I am entirely in agreement with the author in his criticism of the scanty attention paid to the terminals of alternators and motors. The criticism applies also to the methods of leading the connections from the windings to the outside of the carcase in the case of alternators, or to the terminal box in the case of motors. The standardization of terminal and cable-sealing boxes would be a boon to users. To my mind, compound filling is the only solution to all the difficulties encountered at this point, especially on motors, but the motor makers claim that it is difficult to seal the cable outlets against the compound, especially in warm situations. The remedy for this will be obvious to anyone with experience of metal-clad compound-filled switchgear. Transformer oil is indeed very penetrating. Much of the present trouble with junctions of porcelain and metal will disappear when the production of fused quartz on a commercial basis becomes practicable, and that day is not far distant. This material has a very high melting point,

the smallest expansion of any material, is more transparent than glass, is a better insulator than porcelain both mechanically and electrically, and consequently will have manifold uses in the electrical industry. Attention should also be paid to the cement employed with porcelain; I have known both oil and compound to leak past this cement. I agree with the author in regard to the duplication of components, but to be more definite I suggest that if a switch is purchased which is rated for twice the working pressure, twice the maximum full-load current of the circuit, and twice the breaking capacity required (according to the B.E.S.A. rating), then ample reliability will be obtained and there will be no need for spare switches. With regard. to duplicate busbars, the fact that all new stations possess them in some form or other is ample evidence of their necessity. The need for them in substations is dependent entirely upon their position in the network. The desire to be able to change over without making dead is a legacy of the open-type gear. In my opinion the only case which warrants it is that of an open-ended feeder. In all other cases I fail to see why the great advantage of simplicity should be sacrificed for this doubtful one. Until the results of the research at present being made into the design of oil switches are published, the relative importance of each of the factors affecting breaking capacity as enumerated by the author is purely hypothetical. For the same reason B.S.S. No. 116—1923 is not final, but is merely a guide in the matter of choosing an oil switch. Users must still, therefore, rely upon the experience of the makers in this matter and, in addition, for their own peace of mind, revert once more to the employment of factors of safety. I personally, as already stated, specify 100 per cent more than the B.E.S.A rating, and consequently it was with interest that I noted that the author recommends 70 per cent more. To deal with all the factors would take too much time, but there is one point to which I should like to draw attention. The only part of an oil switch subjected to wear and tear in normal routine operation is the brush contact, and heating at this point due to bad contact should be carefully watched by the operating staff. The only safeguard is a periodical examination of the contacts. When purchasing a switch, however, the purchaser should attach as much importance to the millivolt-drop test across the contacts as to the pressure test. Some time ago two accidents, due to the presence of chargers, led us to investigate their utility or otherwise, and oscillograph tests certainly proved their effectiveness during the switching-in of large motor armatures. In my opinion, first in the interests of simplicity, and secondly because they are not always in circuit when wanted, they should be abandoned, but unfortunately some makers of certain types of plant still consider them to be a necessary evil. The author states on page 436 that "delicate fault-settings of relays are sometimes attempted by the use of large current transformers," and I am not quite clear as to his meaning. Does he refer to overload or to Merz-Price protection? Certainly to employ a ratio higher than is really necessary will entail a finer setting of the relay for a given primary fault current, but that anyone should increase the ratio solely with this object is beyond my comprehension. I am glad that the author calls attention to this point, because the indiscriminate choice of current-transformer ratios has an important effect upon the protection. Like chargers, excess-pressure dischargers also may be regarded as necessary evils in some cases. To install such apparatus, however, without a means of indicating whether they function or not is, in my opinion, quite useless. Referring to the subject of safety to men working on the line, is it not possible for the operator accidentally to place the earth contact in Fig. 24 on the busbar plug instead of the feeder plug? Interlocking entails complications and also engenders in the operating staff a false feeling of security. No interlocking system is 100 per cent mistake-proof, and I often wonder if an elaborate sustem might not cause as many accidents, due to over-trust in it, as would arise in a simple system without any interlocks at all. I suppose the solution, as usual, lies in a compromise. There is a plethora of protective schemes on the market nowadays, and improvements in existing schemes generally mean additional relays. Whilst sympathizing with the makers in their difficulties, I am afraid that the inevitable result of it all will be that the bewildered user will, in many cases, regret the departure from the original combined overload and leakage system, which possessed the great advantages of simplicity, robustness and absence of pilots and was easily understood by the operating staff. It is illuminating to compare the schemes adopted in all new stations throughout the world; a few are the simplest possible, others have installed all the schemes and complications in existence, while others have struck the happy medium. Every undertaking has its own peculiar conditions to meet, and if a maker keeps this in mind and concentrates his endeavours towards simplicity and reliability in the direction indicated in the paper, I feel confident that the nearest approach to the ideal system will be reached very soon. I like the term "stability ratio" and the purpose for which it is put forward, but I am rather afraid that users will not be able to employ it with confidence until standards are established for the two factors constituting the ratio. The author makes a similar remark with regard to the rating of oil switches on page 434 and to my mind, since both subjects are so closely related, the same bases might be employed for both. The author quotes stability ratios varying from 25 to 200, and I should be glad to know what in his opinion are good values for generators and feeders respectively. With regard to the neutral resistance, the more one studies the subject of protection the more one is driven to the conclusion that a resistance is unnecessary. It is really a question of stability versus resistance. Both are pulling opposite ways upon the relay settings, stability demanding a high setting and resistance refusing and, in fact, enforcing a lower setting. Viewed from another point of view, the presence of a resistance has one advantage only in that it limits damage to the alternator on the occurrence of an earth fault. In my opinion this advantage is purely theoretical, because exactly how much more the damage would be with a solid neutral can only

be guessed at, especially when one considers the extremely small values of earthing resistances, which values will become smaller and smaller (therefore entailing more and more space occupied) with the rapid increase in the size of alternators. On the other hand the absence of a resistance would afford such definite advantages as: (1) Higher relay setting, and therefore greater stability; (2) complete protection of alternator windings against earth faults; (3) quicker development of earth faults; (4) elimination of cost of resistance; and (5) saving of space required for resistance. With regard to advantage (3), the devotees of the resistance might say, "Not only quicker but more disastrous development of earth faults," and my answer to this would be that, as regards feeders, a more disastrous effect would be welcomed because it would enable faults to be located with more certainty and speed. As regards alternators, however, we come back to the point to which I have already referred as the only—and at that, doubtful—advantage of a resistance. If we assume, however, that it is indeed a definite advantage, is not the correct way of tackling the problem to let the fault develop quickly to a high value and trip it out quickly with certainty, rather than to let it develop slowly and trip it out at a slightly lower value with uncertainty? Let engineers ask themselves which of these two circumstances will cause more damage. Once an earth fault develops, the fraction of time corresponding to the difference in the two relay settings is negligible, and it also should not be forgotten that the fault may develop in that portion of the winding left unprotected due to the presence of the resistance. I do not quite agree with the author when he says that the need for sensitive settings is due solely to the desire to cut down the size of the resistance. It might be so where space is very limited, but in my opinion it is more often in order to protect as much of the windings as possible and to lower the fault tripping current at the same time, simply because it is taken for granted that a resistance is absolutely necessary. I am very interested to hear that the author does not favour the employment of reverse relays for generator protection, but as only one single-phase relay is necessary when used in conjunction with Merz-Price gear, I consider that the extra insurance which it affords is worth the slight extra cost, particularly where alternators vary greatly in size. This type of relay redeemed itself in my views during a recent accident when under a unique set of circumstances one such relay assisted in preventing a total shut-down. Under the title of self-balance the author describes an arrangement for alternator terminals which might well be applied to any machine, no matter what system of protection is adopted. As regards his views upon the sequence of tripping of the machine oil switch, main field and exciter field, this is largely a matter of opinion upon which not only makers but users differ. I can certainly support his statement in his concluding paragraph that overload devices are great offenders in inadvertent operations.

[The author's reply to this discussion will be found on page 1031.]

Western Centre, at Bristol, 4 May, 1925.*

Mr. R. Hodge: One very interesting item which I do not think has been mentioned by previous speakers is the suggested type of switchgear for outdoor feeder work for use in agricultural and outlying districts. I refer to the high-tension switchgear. If this piece of apparatus, after being thoroughly tried out, is proved reliable, it should greatly simplify the supply of electricity to outlying districts, as no doubt its cost will be well below that of circuit breakers.

Mr. C. T. Allan: It would be an advantage if ironclad switchgear could be arranged for phase-changing tails to the cables. It is easier to repair a cable joint after breakdown by allowing the core joints to be made as they come in the road, especially in wet weather, than by forcing the correct phases together. When a new supply is commenced, small-ratio current transformers for metering are necessary on account of the low load, but, when the load increases, larger-ratio current transformers will be installed. This is, however, difficult to do on ironclad compound-filled switchgear. We have attempted to overcome this difficulty by housing the meter and its current transformers in a separate open-type cubicle. It may not be as safe as the other method but it has given us no particular trouble. The cost of e.h.t. switchgear seems to increase at a very much greater ratio than voltage, making the capital cost prohibitive and supplies for rural districts impossible. This type of load will have to be catered for, for many reasons, one being that the farmers over whose land the pole lines run naturally endeavour to insist on a supply being given to their farm.

Mr. T. R. Kernick: When dealing with ironclad switchgear for general distribution, one point I should like to mention is the difficulty encountered when it is necessary to change-over phases after a feeder breakdown and repairs have been carried out, particularly on e.h.t. work. Another difficulty with this class of gear is the trouble experienced in getting at the necessary contacts when mains-testing has to be carried out. This generally involves the removal of the complete switch truck. The author refers to the merits of underground cables compared with overhead lines, especially as regards maintenance costs. With mains laid underground in districts where ground subsidence is common, the maintenance costs can be, and are, very much higher than those of overhead lines in the same area.

Mr. H. R. Beasant: The paper deals only with alternating current, but direct current is still used; for instance we are still employing it for traction purposes. Can the author supply any information in regard to the safe breaking loads on d c. circuit breakers, or in regard to the time taken to get rid of an arc? We have often tried to get this information from switchgear makers, but the reply is usually that "this breaker will break at many times its carrying capacity." If such information is not available I think that steps should be taken to supply it.

* The paper was read at Bristol by Mr. L. E. Mold on behalf of the author.

Mr. T. E. Lewis : Can the author say how the figures for ascertaining breaking capacity are obtained ?

Mr. T. H. Haigh : I gather from the previous discussion that the breaking capacity of a switch depends more on the size of the tank than on anything else. I understand also that the speed of break at the moment of opening is an important factor. It is now common practice for switch makers so to design their tripping gear that if the switch is closed on a fault it trips immediately the contact is made, with the result that at the moment of opening there is no speed whatever. Does this seriously affect the breaking capacity ?

Mr. S. B. Haslam : The paper makes but little reference to the use of metal-clad gear under colliery conditions, yet I think there is no doubt that the development of metal-clad gear is largely due to these colliery conditions. In South Wales especially it is nearly always necessary to use flameproof or explosion-proof gear and, to take one improvement only, there is no doubt that the excessive strength of the tanks and the increased breaking capacity of this class of gear have been brought about because of the precautions which are necessary for underground working. Mr. Allan mentioned certain conditions which have to be taken into account very carefully, especially at the present time when finance is the predominating feature. These conditions are of course due to the development of electricity in underground working, and it is really a very serious matter and one which requires careful consideration. Personally, I consider there is a great deal of danger in an indiscriminate use of reactors, and it is necessary that all conditions should be taken into account before they are used. Another source of trouble which is frequently overlooked is the question of relative speed in operation of different types of switches in series. In a recent experience a small modern distribution switchboard was connected by a short length of cable to a circuit breaker on the main board of a large power station. The large switch was intended to deal with bad faults and to protect the smaller switches, but owing to the smaller modern switches operating more rapidly they were disastrously stressed. In such circumstances a definite time-delay device must be used which will ensure the larger switch operating first for a heavy current fault, but for a small current fault the smaller switch may clear the circuit at the expiration of the time-delay. It is hardly necessary to emphasize the fact that the very greatest care should be exercised in the selection of materials used in metal-clad gear. The other point to which I should like to refer is the connections to the machines. It does seem absurd that whilst carefully designed boxes are considered to be a necessity on a switchboard, the cables are frequently connected with the machine in a haphazard manner. The paper shows us that the author has given a considerable amount of thought to this important point, and I should like to suggest that far more attention could well be given.

Mr. H. W. Clothier (*in reply*) : I propose to deal with the various points raised under the headings of the Centres where they were discussed.

Newcastle.

The discussion at Newcastle is significant, coming as it does from the home of complete metal enclosure, where there is plenty of experience as to its design and working conditions. Apart from a general agreement with the several contributions there are a few specific points which call for a detailed reply. I feel sure there is much in Mr. Gregory's statement in regard to automatic indication and supervisory control. I am satisfied that the future will bring a greater demand for designs to relieve much of the very onerous operating which is performed to-day by hand. The greater uses of electricity and the concentration of enormous power will call more and more for automatic control. Otherwise the responsibility of making rapid decisions correctly, especially during emergencies, would be likely to become almost intolerable. These thoughts lead me to disagree with such comments as those made by Mr. Cresswell at the expense of interlocking features. Admittedly, every interlocking device must be perfected, and I believe that with care it can be. After all, automatic control and automatic supervisory control are in themselves advanced interlocking features in that they reduce the chance of human error by placing the sequence of operating functions into a regular order.

Mr. Williams suggests an appendix showing total switch-house costs, including building. I agree that this would be instructive as a commercial basis between different types of switchgear, but I suggest that it does not come within the scope of a paper the purpose of which is to consider safety to life and security to supply. Moreover, there is difficulty in making a straight cost comparison owing to the great divergence in practice, in the layout of connections, duplication of switches, in the margin allowed on insulation and clearances and in other ways, but a comparison of building constructions between draw-out metal-clad switchgear and a well-known example of cell type switchgear in America is shown in cross-section in Fig. E. The circuit breakers have the same rated breaking capacity, although in the metal-clad gear the tanks and top plates are larger and stronger, and therefore may be said to have a larger factor of safety.

The footnotes in the paper are intended to give credit very briefly to the originators of the designs which are recorded.

The semi-fluid compound referred to is a heavy mineral oil which is suitable for filling chambers when the contents are required to be accessible. It flows sluggishly at 16° C. and freely at 60° C., and its specific gravity is 0·88 to 0·92. As it is fluid at the permissible temperatures of switchgear, oil-tight joints are usually essential.

Mr. Thornton's testimony in regard to decreased costs of maintenance and repairs should be noted. The time of shut-down in making busbar extensions may be reduced by the initial erection of busbars in complete sections with section switches or in the use of duplicate busbars, but as a matter of a practice it is usually possible for a skilled erector to make a busbar joint in an hour or so. Other work on extension parts may be carried out in safety up to this juncture, as only

earthed metal is accessible, even when an adjacent existing panel is alive. A tee off a split-conductor line can always be taken satisfactorily through a single split-conductor switch. In this respect the choice of protection is equally favourable to split-conductor and Merz-Price voltage-balance protection. But I agree with Mr. Thornton that the split-conductor system accommodation laterally on alternator end-shields for the three terminals in line. In the future if end-shields are made deeper for other reasons it may be convenient to revert again to the design shown in Fig. 36 (I refer him to Mr. Buist's contribution to the discussion). At all events I am glad to have his views on the routine of breaking field circuits, and agree to the necessity for

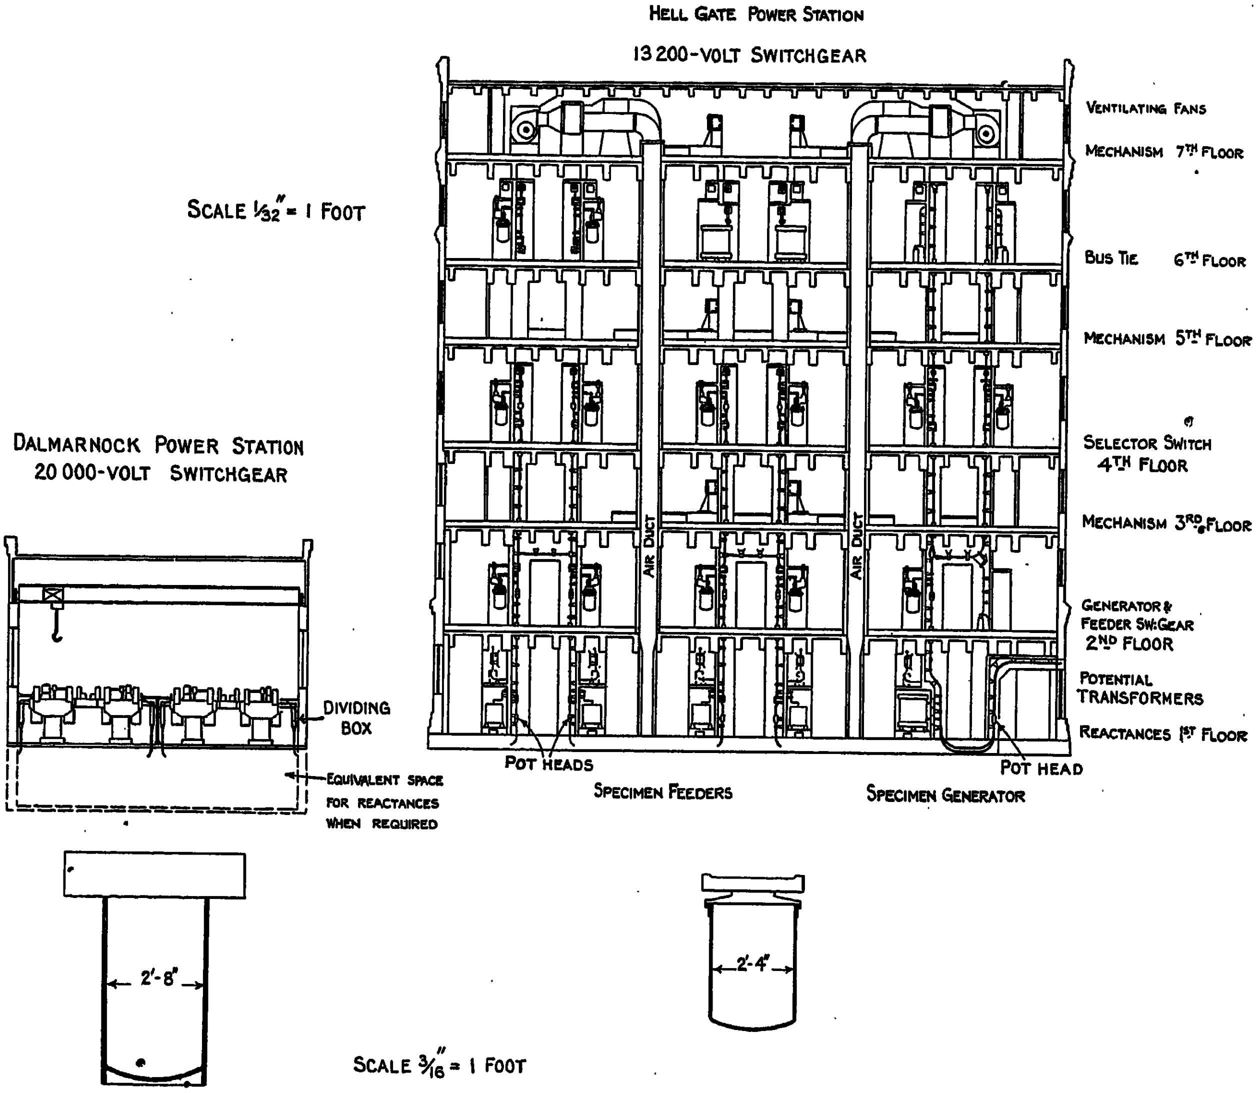

FIG. E.—Comparisons between Heil Gate and Dalmarnock power stations.

Upper figures (scale $\frac{1}{32}$ in. = 1 ft.)

Metal-clad gear, four panels, duplicate busbars, section through single phase. Single circuit breaker and two oil busbar selector switches per panel.

Open-type gear panels for two feeders or one generator section through three phases, duplicate busbars with two circuit breakers per feeder and three circuit breakers per generator.

For controlling a given number of generators and feeders the lengths of these two buildings would be approximately the same.

The lower figures (scale $\frac{3}{16}$ in. = 1 ft.) show the relative sections through the circuit breaker tank and top plate; both are rated at 1 500 000 kVA.

of feeder protection is inconvenient on feeders with tees when the tee is to be protected by a fuse for the sake of economy. It involves the use of a balanced reactance on each tee; these are not desirable additions to the switchgear apparatus.

I am disappointed that Mr. Rosen cannot find very sound construction of switchgear for power station auxiliaries and on self-balance protection. The importance of extinguishing the fire following a fault on the winding is felt so acutely that in some places a fire-extinguishing spray is contained within the machine. The speedy action of self-balance protection in isolating

the machine and simultaneously opening the field should go a long way towards the reduction of fire risks and the extent of damage occasioned by a fault. The world-wide use of one or other balanced systems for alternator protection is a striking acknowledgment of the pioneer work on protective systems done in the neighbourhood of Newcastle by the local power undertakings just on 20 years ago.

I would commend Mr. Leeson's alternative treatment of dealing with the need for a recognition of some form of stability factor to the British Engineering Standards Association, as I see no better means of encouraging a high standard of efficiency in this respect than by having an attempt made to establish the terms and measure of efficiency of protective systems. I agree that the minimum "stability safety factors" should be as follows :—

For voltage-balance feeder protection	2
For split conductor	4

(since the larger factor is easier to secure, retaining a light fault setting).

For generator protection current balance	4
For transformer protection current balance	2

The above figures to include all known hazards such as the magnetizing-current transient on transformers and resonance phenomena on feeders.

As a specification for protective gear one would include the following particulars :—

	Proposed standard terms
Required factor of safety between the actual service settings of relays and the test-room result on a circuit with equivalent characteristics	"Stability safety factor"
Maximum straight-through current possible between phases in the line to be protected with the ultimate amount of power plant behind, and making allowance for the impedance of all connections and intermediate equipment	"Straight-through" current
The minimum primary fault current between phases required to operate the relay in practical service	"Phase fault" current
Ratio : $\dfrac{\text{Phase "straight-through" current}}{\text{Phase "fault" current}}$	"Stability ratio" or "efficiency factor"
Minimum earth fault primary current to trip relays	"Earth fault" current
Maximum straight-through current to earth faults, having regard to the limitation of current imposed by the resistance of the return path via the earthing resistance	"Earth straight-through" current

Note.—When considering possible easement due to the "earth straight-through" current being less than the phase "straight-through" current, the adverse effects of simultaneous earth faults on different phases should not be overlooked.

I am in full agreement with Mr. Mold's reasoning in favour of the method of changing over from one busbar to another shown in Fig. 8. All the systems may be equally well interlocked to prevent mistakes and accidents, but with a varying degree of complication. The figures being only diagrammatic the interlocks are not shown, but it must always be the safer and simpler plan to open the circuit before effecting the change-over. Mr. Mold asks for a reliable expression of opinion on this subject. Other contributors have discussed it. I would refer him to the remarks by Mr. Townley and Mr. Lovell, also to those by Mr. Buist, who declares that "the desire to be able to change over without making dead is a legacy of the open-type gear."

Given a suitable layout of cables and plant, it should be possible for any one switch to be open without interruption of supply. Unfortunately some systems, e.g. single feeders starred out, are deficient in this respect. In such cases it is impossible to open any feeder switch without causing an interruption, and therefore occasions do arise in which it is out of the question to effect a change-over unless it can be done with the circuit alive. The need for such schemes as shown in Figs. 9, 10, 11 or 12 appears to be brought about entirely by these shortcomings in some system layouts. Owing to the greater operating dangers and interlocking complications of changing-over under load, it is best to continue with the simple plan shown in Fig. 8 in all ordinary situations.

Loughborough.

Mr. Wilmshurst agrees that metal-clad switchgear eliminates danger, but begrudges it the features of non-access which is the means by which that security is obtained. My best reply is to refer him to other speakers who are users of metal-clad gear, particularly those included in the Newcastle and Leeds discussions, but in addition I would suggest that it is a delusion to expect on large cell-type gears that the conductors form their own diagrams. It used to be so, but since they have grown and are now scattered upon different floors and compartments this advantage can

no longer be substantiated. If it applies at all it is to metal-clad gear nowadays, because the whole of the conductors are usually to be found upon one floor, and the path of the primary conductors could readily be painted upon the outside of the metal casing.

Mr. Wilmshurst makes a point of the possible need for increasing the sectional area of the busbar. When a station grows from small beginnings a time arrives when the switchgear originally installed, unless made large enough for the ultimate growth, must be taken out and, if it is in good condition, it may be moved to some less onerous situation. It is in such cases insufficient merely to add copper to the busbar sectional area, indeed that addition to large power station gear is a most unusual demand, for the reason that such gear is generally made up in sections of generators and outgoing feeders, each section carrying its own load from its generators. If a new generator is added it is usually because there are new feeders also, and these form the nucleus of a new section premeditated when the plant was first installed. The supposed impossibility of making additions to the sectional area of an existing busbar is not a material objection. One might almost as well call it an objection to cables and generators that their copper cannot be increased. It is not done. The demand in such cases is met by putting down new plant as extensions.

Mr. Wilmshurst inquires as to the protection of unit transformers for auxiliaries in large generating stations. These may be coupled on the high-tension side direct to the terminals of the alternator or to the switchgear, whichever is the shortest route for the cables. One switch panel controls the generator, its unit transformer and the cables. The automatic protection, whether Merz-Price current balance or self-balance, would have one common secondary system and relays.

I believe that the tetrachloride fuse serves a useful purpose economically when mounted well away from any operator. Its suffocating fumes must be a restriction otherwise. The fuse chamber in Fig. 27 contains nothing but ordinary switch oil. Any corona discharge inside metal-clad gear would be distinctly dangerous. Just as with open-type gear, it tends to weaken the insulation by forming nitrous acid. One feature of the metal-clad construction is that the compound- or oil-filling prevents internal air spaces and so avoids corona.

It will be of interest to present-day switchgear designers to hear of Mr. Driver's experiences with the water-break switches which form part of the early Rayworth pillars. These, with the exception of the actual switch, were pioneers of metal-enclosed construction. Mr. Driver's experiences with lightning arresters is confirmed by other speakers, and the subject is discussed below (see also the discussion before the Institution and my reply thereto).

Mr. Hall's experiences with pole-line insulators and switchgear on first consideration seem to point to an insufficient factor of safety in initial design, but this of course requires a closer investigation than I am able to make on the information supplied.

In reply to Mr. Field I will assume that the angle of lag of the short-circuit current is increased by additional reactance, and that an oil circuit breaker severs the arc, at the first zero value in the current wave, on short-circuit at unity power factor with comparative ease. With lag in current there is a tendency for the voltage to maintain the arc, and at a critical phase angle the arcs might be reinstated in passing through the zero value of the current wave, and hence the arc is prolonged and the arc energy thereby increased.

The temperature-rises for busbar densities in Fig. 13 are within the British Standard Specification No. 116, namely 30 deg. C. up to and including 2 000 amperes, and 40 deg. C. over 2 000 amperes. I am unaware of any trouble at the juncture of cables and lines directly attributable to the form of excess-voltage dissipation advocated in the paper and elsewhere in my reply. There are many thousands of miles of lines so protected at all recognized pressures up to 66 000 volts in this country. It is notably a standard practice on the North-East Coast. The several causes leading up to the complexity of the balanced protection systems shown in Figs. 32 and 33 are described in the paper. It does not follow that because some exceptional cases warrant this complexity that protective gear is getting more complex than ever. All new efforts must be directed towards simplicity, but reliability and stability have the first claim upon the design.

Fig. 20 is a diagram of busbar layout. It is not to be supposed that it represents the geographical position of the generators. The vertical upward isolation simplifies some of the constructional framework and gearing for large sizes, as shown in Fig. 7, when a crane common to all units is available for raising the removable portion and for transferring it to an inspection bay or to another unit. Moreover, the arrangement eliminates much man-handling, and has a time-saving advantage for massive circuit breakers during the process of erection and maintenance operations. Had Mr. Field taken time to consider the full circumstances the arrangement would not perhaps appear to him "to be a very unsatisfactory layout." At any rate it is one that appears to fulfil the requirements of four of the large power stations in this country, indeed, I believe, in all the power stations in this country which contain any appreciable numbers of circuit breakers of over a million kVA breaking-capacity rating.

Leeds.

Over 50 points worthy of serious attention were raised at this Centre, and I am gratified to receive such appreciation of the principles set out in the paper entirely from engineers competent to speak with authority upon users' experiences. These points include significant comments upon excess-pressure discharge, stability of protection, relative safety of different types of switchgear, duplication of switches and busbars, and the changing-over thereon, breaking-capacity ratings and other important subjects, and I should prefer nothing better than that they should be read as replies to criticisms of those speakers in other places who appear to be less practised in the essentials of satisfactory operating requirements. In consequence of the numerous comments I may perhaps be excused, without risk of being thought negligent, from full discussion of the

subjects already included in the preceding reply, if I deal mainly with the other items.

I understand that Mr. Howard Brown wishes to consider how the principles of protection which have been discussed for alternating currents can be applied to d.c. plant. I believe that the metal-clad enclosure and draw-out gear is suitable and desirable for safety; there are many existing instances of oil-break d.c. metal-clad switchgear for pressures up to 3 000 volts. The circuit-breaking problems are more difficult. The arc energy is greater and more vicious than the corresponding capacity in alternating current. Thus the design of the circuit-breaker portion must be adjusted to suit the more severe conditions. As to discriminating systems of automatic protection, I know of one system of leakage protection which operates on out-of-balance between the current in the positive and negative leads respectively. The reverse-current relay as a discriminating device has no disrepute that I know of, and of course the automatic-control d.c. substation plant is well known and is making considerable advance as an example of automatic and interlocked sequence of operations.

The fuse for potential transformers is a somewhat delicate device at its best; the addition of a separate resistance in circuit with it only adds to the frailty of the whole potential-transformer circuit, but a resistance combined within the fuse itself is a possible solution of the desirability of reducing the amount of short-circuit current which may pass in the event of a fault beyond the fuse. A high-resistance fuse * may also find useful scope as a protective device for comparatively small high-tension feeder circuits, but I would consider the addition of a separate resistance to a small high-tension feeder a risk as it introduces another weak apparatus with its own set of insulators, which are additional parts to maintain and protect.

I think that Mr. Townley's record of experiences on open-type switchgear are of exceptionally notable value and the attention he has drawn in the past, and now repeats, to earthing resistances and the stability of protective systems will have more effect than anything I can say. He gives timely advice in respect to changing over from busbar to busbar; he says "such operations are infrequent and should never be done hurriedly." He speaks of the inefficiency of concrete barriers in isolating an arc once started on switchgear with about 50 000 kW of plant running, and says that extended experience of the behaviour of metal-clad gear under such conditions has yet to be gained. Under no circumstances is it possible for the arc to spread from conductors on panel to panel, for the obvious reason that no metal but earth metal is exposed. An incident is on record where a dead short-circuit was made on metal-clad switchgear due to a constructional mischance when 75 000 kW of plant at the station was running in parallel with a similar amount of plant at other power stations. The entire damage was localized to the faulty switchgear panel and, notwithstanding the violence of the shock to the switch house, not a single consumer or generating plant was interrupted. The only other effect was to burn out an earthing resistance for which one of the generators was afterwards shut down by hand. In contrast with this the Calumet switchgear referred to by Mr. Gregory was reported in the *Electrical World* recently to have caused a complete cessation of supply to parts of Chicago. This was owing to an arc being drawn out and spreading over several panels on one phase; the trouble was even communicated to another phase of the switchgear, notwithstanding the isolated phase construction of the building, and was due to the operating rods becoming damaged. As one speaker said, "the open-type switchgear gives the arc a free ticket." There is available for reference at least 15 years' experience of metal-clad switchgear working in power stations on systems where the plant capacity is equal to or more than that mentioned by Mr. Townley. In every instance of failure known to me the trouble has never spread beyond the part of the panel at the root of the disorder. Mr. Townley asks for the breaking capacity of circuit breakers, but this can only be determined from experience under operating conditions, although I agree that the most useful basis among numerous other characteristics is the volume and strength of tanks and top plates. No further amplification upon the contents of the paper can be more convincing than service experience. Even prearranged tests may mislead because they provide for everything in test-room condition, whereas the greatest stresses in circuit-breaker tanks are to be encountered when the unusual disorder happens, such as accidental sustained arcing. Sheer mechanical reliability is the all-important factor. This can be gauged by inspection and years of service, but cannot be reduced to a formula in the present state of the craft.

* Patent No. 227928 and Prov. Specn. 8686/1925.

The report of Mr. Longman's contribution does not record all that he said, but his criticisms in regard to connecting up protective gear and the need for efficiency in all directions, both as regards the prevention of, as well as the release of, faults are warranted. I am not aware of any breakages attributable to right-angle bends in compound-filled boxes. He draws attention to the single-switch substation equipment (Fig. 28) as a scheme requiring examination from the point of view of reducing switchgear costs. In reply to his question the voltage-balance protection transformer extends so far over the tee as to operate in the event of a failure of the switch fuse.

Mr. Jones also refers to relative efficiencies. It is unusual for manufacturers not to state a breaking capacity, but the actual meaning of the amounts given is frequently obscure.

Mr. Lovell refers to a point mentioned also by Mr. Bridges at Newcastle, viz. the need for some device to close from a distance a switch which controls a doubtful circuit. A device once called an "iron hand" was made for this purpose. This was in the form of as portable weighted lever which could be attached to a switch handle, the weight being tripped over into action closing the switch by a cord pulled from a distance. Other devices for a similar purpose consist of ropes attached over pulleys to obtain the right direction of force in closing a switch directly. These may be some comfort to an operator in an awkward situation, but such safeguards if provided are likely to be missing when most required. The best policy, of course, is to

install switches in all positions which have sufficient rating to withstand closing on a fault without danger to any operator, whether the switch be in a cell or remote-operated ; in any case the safety of the person who happens to be standing by the switch has to be considered, as well as that of the person actually making the operation whether directly or from a distance.

Referring to Fig. 3, the centres of terminals on transformers are sometimes so wide apart as to prevent the use of a direct three-core cable dividing box, otherwise I agree that they would be preferable to the single boxes in the case stated. On the self-balance protection the lead sheath of the cables is insulated from earth at "C" (Fig. 37) and therefore the resultant unbalance due to the fault-current circuit will energize the protecting transformers "D," and thereby operate the protective system.

Mr. Buist's considered communication is rich in practical experience. I have already referred to some of his comments. Regarding his reference to page 436, in order to obtain sensitive trips on certain modifications to Merz-Price protection using current-balancing and biased relays large current transformers have been used. These on open-circuited secondary would give high secondary voltage. For example, a 40-VA transformer when passing 300 amperes (primary) gave a secondary pressure of 1 200 volts on open-circuit. Moreover, transformers of 150 VA have been recommended for longer lines. The corresponding open-circuit voltage would be a source of danger to anyone who might be handling the secondary leads under the impression that they were at low tension. Compared with voltage-balance with single-primary-turn air-gap transformers, a primary current of 300 amperes gives about 12 volts on the secondary, and a momentary maximum of 400 volts is attained only in the event of a short-circuit of 10 000 amperes passing through the primary.

Both Mr. Buist and Mr. Lovell refer to the earthing device shown in Fig. 24. One phase only should be earthed first always. The busbar chamber should be locked off in order to avoid the risk of an operator accidentally earthing the busbar. Sometimes a locking keyway or some such device is added ; this permits the earthing plug only to be applied in the required position. I agree that such precautionary measures are desirable to avoid mistakes. In one instance an operator locked off the correct door, but his superintendent, thinking he had made a mistake, deliberately unlocked the door and inserted the earthing plug in the live contacts.

The following suggestion for "stability ratio" or "efficiency factor" should be read with the stability safety factor figures given in reply to Mr. Leeson.

Voltage-balance feeder protection on the ordinary simple case, an average of	25 : 1
With added apparatus like the diverter relay system ; providing lighter setting when imperative	100 : 1
For generator protection with ordinary current balance and impedance relays	100 : 1
With the addition of bias or diverter relays when lower fault settings are imperative ..	200 : 1

Mr. Buist's contribution to the question of earthing-resistance values is opportune and serves as a more complete reply to Colonel Edgcumbe. The point for their retention, namely, the saving of the alternator, I agree should be met by using a resistance of low ohmic value. This increases the size and consequent cost as shown on the approximate curve, Fig. F, but I believe that the solution, so far as economy is concerned, will be found in the wider use of water resistances.

I trust that the foregoing discussion will lead to a further advance in the science of switchgear engineering and that this section will achieve a future record tending to free the uses of electricity from risk. The fact that electricity is safer than other contemporary power agents, e.g. gas, should not be taken, as it sometimes is, as a narcotic to smooth over the accidents which do occur, however infrequent they may appear to be when considered on the basis of comparative statistics.

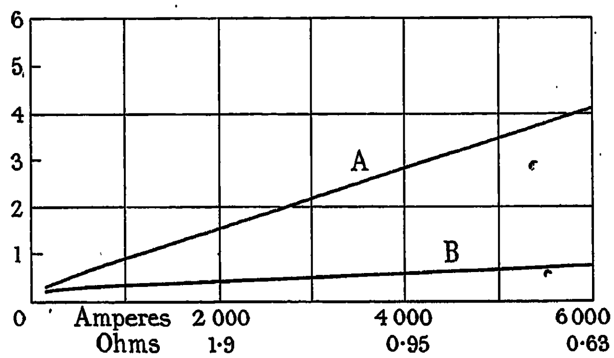

FIG. F.—Approximate cost of earthing resistances on a 6 600-volt system, showing increase in cost with reduction in ohmic resistance.

Curve A.—Costs of grid resistance.
Curve B.—Relative possible cost of liquid resistance.

Bristol.

Mr. Allan's proposal to have accessible change-over links on metal-clad switchgear for the purpose of avoiding the necessity, when repairing a cable, of taking notice of the correct "lay-up" of the phases, has been put into practical application, but it seems to be a refinement hardly justifiable in view of the complication. Moreover, the accessibility of any conductor on switchgear is a source of danger of the kind which metal-clad switchgear in general construction is intended to avoid. In a similar way current transformers have been enclosed in semi-fluid compound so that they are accessible on the removal of a cover. The usual plan, however, is to install current transformers in the first instance of a ratio large enough to anticipate the future demands of the circuit. Another method adopted by some undertakings and, I believe, first employed at Sheffield, is to standardize certain current ratings and when, as in the case of a wattmeter circuit, it is required at the commencement to have a low wattmeter reading, the removable portion of the panel is, for the time being, replaced by one having wattmeter current transformers mounted as an integral part, the whole forming a low-reading wattmeter unit combined with

the circuit breaker. All that is necessary then, when the consumer's load increases, is to withdraw the wattmeter unit and replace it by the standard circuit breaker. This avoids any alterations to connections; it can be very quickly done, and it eliminates any possible danger which might arise from the handling of accessible high-tension conductors. The cost of very high-tension switchgear is certainly prohibitive for small supplies if complete panels with circuit breakers are employed for scattered areas, such as farms and rural districts. The switch-fuse, as illustrated in Fig. 27, is one means adopted to deal economically with such conditions.

Mr. Kernick's point in regard to cable jointing is similar to that referred to by Mr. Allan. In most makes of metal-clad switchgear the cable-testing connections are easily inserted into the orifice sockets which are available when the removable portion is withdrawn. The attachment of such connections to bare conductors on open-type switchgear is frequently a source of danger to the operator owing to the risk of the conductor being inadvertently alive. In metal-clad construction the risk is to some extent reduced, particularly if correct precautions are taken in the design and application of earthing devices, for example, as illustrated in Fig. 24. When making the usual low-tension tests it is preferable first to use the device indicated in Fig. 24 to earth the cable, and then to take the testing connections from the top contact of the switch in place of the earth connection. For high-tension tests, jumper cables to plug into the orifices are substituted for the removable portion. On the whole the risks attendant on making special connections, for testing purposes, to high-tension conductors are reduced by the suitable application of correct metal-clad principles.

Mr. Beasant infers that, whilst much attention is given to a.c. problems, direct current does not have so much as it merits. The metal enclosure of d.c. switchgear is equally desirable, especially on the high voltages now in vogue for railway service. The enclosure and breaking capacity have been discussed in reply to Mr. Howard Brown. I would also refer to the tests recorded by Mr. Collis.* It would be opportune for some up-to-date tests, breaking direct-current short-circuit currents under oil, to be made. This would be a suitable subject for the attention of the British Electrical and Allied Industries Research Association. Circuit breakers of the draw-out oil-break metal-clad type have been used to some extent. Whilst it is true that the demand for those of large breaking capacity is not so general as in the case of alternating-current service, considerable attention is now being paid to the development of high-speed circuit breakers for the protection of converting plant against commutator flashing, which is a step in the direction required by Mr. Beasant.

In reply to Mr. Lewis, breaking capacities are

* Paper read before the South Wales Institute of Engineers, 1911.

obtained from the results of experimental data in breaking short-circuits on alternators, coupled with a close observation of the operation in practical service. The latter is of the greater value in that larger short-circuit fault currents occur accidentally than can be obtained voluntarily by plant at present at the disposal of British manufacturers. As mentioned elsewhere, I know of no infallible formula for calculating the breaking capacity of a circuit breaker from dimensions and characteristics. (See also my reply to Mr. Townley and Mr. Field.)

I agree with Mr. Haigh that of all the circuit-breaker characteristics the strength and dimensions of the enclosure are of primary importance, and possibly he is correct in placing the speed of break next. Most modern circuit breakers have a good kick-off spring release which comes into operation immediately the circuit breaker is tripped. The velocity at the separation of the sparking contacts must be greater when a circuit breaker opens from rest than when opening at the moment of engagement of the sparking tips during a closing operation on a fault. I should not expect this to have an appreciable effect on considerations of breaking capacity. In any case, when closing a switch on a fault there will be a certain lag occurring in the operation of the mechanism which will allow the sparking contacts to travel inwards a short way prior to the reversal of direction. This short distance, however small it is, is enough to allow the sparking contacts to acquire momentum prior to the actual separation. It is possibly true that closing a circuit breaker on a short-circuit is worse than opening on a short-circuit, as there is first the arc disturbance on making contact, and secondly the arc disturbance on breaking contact. This may be a more serious consideration than the velocity at the moment of the contact separation.

Mr. Haslam's remarks are of great importance, particularly with reference to the necessity for the careful determination of the maximum possible short-circuit currents in the several positions in mines. Nowhere has there been such a great progress in the development of large power plant for the application of electricity in mines as in South Wales. For example, there are power stations of large aggregate capacity generating at 3 000 volts practically at the pit heads, and the safety factor in such circumstances cannot be too greatly emphasized. There is a report* existing on the maximum short-circuit currents likely to obtain in several positions in mines.

I confirm also the necessity for careful attention to the relative time function of circuit breakers when two or more circuit breakers of different breaking capacity are connected in one circuit. It is possible by the correct adjustment of definite time-lag to allocate the breaking duty on the heaviest short-circuit currents to the most efficient breaker, which, in many cases, may be preferable to the indiscriminate use of reactances.

* B.E.A.M.A. Technical Committee Report, October 1924.

DISCUSSION ON "SOME RESEARCHES ON THE SAFE USE OF ELECTRICITY IN MINES." *

SHEFFIELD SUB-CENTRE, AT SHEFFIELD, 19 NOVEMBER, 1924.

Professor D. Hay: We have for some years conducted at Sheffield University a standard test for flameproof qualities of commercial electrical apparatus—a test of a limited character based on the earlier work of Thornton, Wheeler and others. Although the conditions of this test do not perhaps go as far as we should like, I feel convinced that this work has served a useful purpose in establishing some kind of limited standard for such apparatus, and this is far better than having no standard at all. It is within our knowledge that the result of the tests has been to cause many modifications in design, and personally I feel satisfied that apparatus designed in accordance with the best recent designs is extremely unlikely to fail in practice. Looking back over the past 15 years, I note that there has been an enormous improvement in the standard of construction, installation and maintenance of electrical apparatus for use underground, and I look for still further advances, following the train of research work such as that described in the present paper, backed up by the efforts of the manufacturers.

Mr. I. C. F. Statham: The conclusions at which the author has arrived are interesting, but before proceeding to apply them in the mine much careful research work is still necessary to ensure that the conditions he lays down are within the safe limits, particularly since the results obtained by Prof. Wheeler are not in consonance with those recorded in the paper. In this connection some results obtained in routine tests of electrical apparatus in the Testing Department of the University of Sheffield also appear to conflict with the author's conclusions. I refer to tests made upon the limiting current permissible with an automatic relay for mining use. In these tests it was found possible to obtain ignitions of firedamp-air mixtures containing between 8·39 and 9·13 per cent of methane with a single-phase current of 1·22 amperes at 100 volts with a frequency of 50. This result was obtained with inductive circuits having a power factor of 0·869, whilst with a practically non-inductive circuit having a power factor of 0·987 the igniting current was 1·60 amperes. It may be remarked that ignition was not obtained every time the circuit was broken, but that a considerable number of "breaks" were necessary in some cases. For example, in one test the operating switch had to be opened and closed 46 times, giving 92 breaks of the relay circuit, before ignition occurred. From these results it would appear that the minimum igniting current values given by the author in Fig. 9 are much too high; they serve to emphasize the necessity for a careful investigation into the question before the conclusions embodied in the paper are applied under the conditions which exist in mines. The author refers to the difficulty of obtaining consistent results in experimental work involving repeated breaks of the circuit, as in the tests to which I have referred. He suggests that the results are vitiated by alteration of the surfaces of the contacts by the development of "hot spots" and the production of irregularities of "spikes" on the contact surfaces by repeated breaks. Whilst agreeing entirely with this, I suggest that such things would occur in practice, and must be taken into account in experimental work having for its object the determination of the limits of safety. If the contacts suffer in this way in the laboratory and reduce the safe current, they will be affected similarly in practice, as they are not taken out, readjusted and polished after each break in order to give consistent break flashes. The author also refers to the influence of the rate of separation of the contacts. This again is difficult, if not impossible, to regulate in practice, but it may be added that, in the tests referred to, the separation of the contacts was electrically controlled so that the rate of separation would be more uniform than when operated by hand. Of greater importance than the above considerations is the fact that with alternating current the result of a single experiment is likely to be misleading, as it is only by the merest chance that the "break" would occur with the current at peak value, and the object of repeated trial was to obtain incidence of current peak and the breaking of the circuit.

Table A gives the more important results of the tests :—

* Paper by Dr. W. M. Thornton (see vol. 62, pp. 481 and 918).

TABLE A.

Test No.	Conditions of tests		Power factor (approx.)	Composition of explosive mixture. Methane, per cent in air	Remarks
	E.M.F.	Current			
	volts	amps.			
161*a*	100·0	1·22	0·869	8·75	Ignition of turbulent mixture after several operations of relay
161*b*	100·0	1·22	0·869	9·13	Ignition of quiescent mixture after 23 operations
161*e*	100·0	1·60	0·987	8·60	Ignition after 46 operations
161*f*	99·1	1·22	0·860	8·39	Ignition after 38 operations

The igniting currents in all cases are considerably below those given in the paper, and in spite of the author's remarks I consider that these results indicate the necessity for a careful inquiry into the whole question before the position can be considered satisfactory from the standpoint of safety, which is the common goal at which we are all aiming.

Mr. H. W. Walker: The tests carried out, and the results shown in the curves, confirm what has been in my mind for quite a long time. In view of Dr. Wheeler's remarks I am rather diffident in mentioning it, but I think it is quite time that d.c. supply was disallowed in the pit altogether. My business is chiefly in connection with breakdowns of underground electrical plant, and from my own fairly wide experience I may say that failures are quite 50 per cent higher with d.c. than with a.c. plant, hence this is a danger additional to those indicated in the paper. I should very much like to hear the author's opinion regarding pit lighting with 25-volt 150-cycle supply, which I think would be satisfactory and safe values, and how this is to be carried out. In my opinion lighting is not required along the whole distance of many pit roads, but chiefly at the coal face, in haulage and pump houses; whilst at road junctions as well as at the shaft bottom it is essential. As one must consider the voltage-drop and cost of wiring to install lights at an a.c. voltage of 25, with a frequency of 150 cycles, I consider that the most satisfactory and safe method would be to use small motor-generators which could be installed in a haulage or pump house in the district in which lights are required. These small machines can be constructed in flameproof cases, and can be run off the normal power supply, whatever it may be, and would be under the control of the regular haulage or pump attendant. The capacity of the generator need be only about 1 kW in many cases, and in such instances it would be impossible to attain a dangerous current, even in the event of a short-circuit.

Mr. F. O. Hunt: I should like to draw the attention of the younger and Student members to the importance of the many side-line investigations of this research as throwing light upon the mechanism of gaseous combinations. On the question of the importance of ionization in bringing about combination I would suggest that the extra activity of nascent gases so long known to chemists is probably really a matter of the greater number of free ions present in gases under such conditions.

Mr. L. H. Crowther: I should be interested to know the approximate resistance necessary for the shunted signalling bell. I assume it is wound non-inductively. Regarding the question of a.c. versus d.c. systems of supply, I can confirm the author's statement from my own experience in a steelworks with which I am connected. The plant and distributing system are fairly evenly divided into a.c. and d.c. groups, and although installed at approximately the same time the troubles due to insulation breakdowns on the d.c. system are quite appreciably greater than those experienced on the a.c. system. I was interested to see the suggested method for ensuring a low-resistance earth, and I believe that the author gave a figure representing the resistance of the earth. How was that figure obtained and what distance apart were the two points between which the resistance was measured? The nature of the intervening ground would no doubt affect the value to a greater or less extent.

Prof. R. V. Wheeler: I understand that the inductance of the circuit in the experiments recorded in Fig. 5 was low and that perhaps accounts for the difference between the author's results and my own. Using direct current at 35 volts with 0·095 henry inductance, and alternating current at 25 volts (R.M.S. value, 35·3 volts crest value) with 0·098 henry inductance, 50 cycles per second, I have been unable to find any material difference in the igniting current required for mixtures of methane and air by break-flashes produced mechanically at platinum contacts. I give below some typical results:—

	Methane, per cent	6·15	7·10	7·60	8·00	8·50	9·00	9·60	10·20	10·90
Igniting current, in amps.	Direct	0·43	0·30	0·26	0·24	0·24	0·25	0·28	0·32	0·42
	Alternating (crest values)	0·49	0·36	0·30	0·26	0·24	0·25	0·26	0·30	0·44

Since I had not the facilities to experiment with alternating current at a higher frequency than 50 I asked Mr. J. D. Morgan, of the Marks and Clerk Laboratory, if he could do so. He describes his experiments in a letter to me as follows: " A small alternator giving a good sine wave was arranged in a circuit containing the ignition apparatus, an air-core inductance coil, a resistance and a hot-wire ammeter. Provision was made for including in series with the circuit a small accumulator as a source of direct current. In the direct-current experiments the alternator rotor was fixed in the position of maximum inductance, and the current from the battery was adjusted until the spark obtained on breaking the circuit was able to ignite the gas. Subsequently the battery was removed from the circuit and current was generated by the alternator, the resistance of the circuit remaining the same. The excitation of the alternator was varied until the least igniting spark was obtained. The results of experiments with an 8·5 per cent methane-air mixture were as follows:—

	Igniting current, in amperes		
	R.M.S. value		Peak value
Direct current	—	0·415	—
Alternating current, 68 cycles	0·285	—	0·41
Alternating current, 200 cycles	0·300	—	0·42

It will be apparent that the results for alternating and direct current are practically the same."

Mr. H. E. Yerbury: As I understand the subject matter, the author's researches and conclusions lie in the application to and safety for mining work of an alternating current of low voltage and comparatively high frequency, as compared with a direct current. No theory can be held to be entirely satisfactory unless it can be justified by actual demonstrations. I believe that phenomena are determined by conditions; therefore if the conditions are altered different phenomena are manifested. I should be glad if the author would indicate what means or what type of apparatus or machine he would recommend to furnish this a.c. energy, which presumably should be at unity power factor with no stored electromagnetic energy anywhere. It is common knowledge that the intensity of a spark or switch or other contact is far greater with a low power factor, and conversely the absence of self-induction minimizes the intensity of any spark. Are we to understand that if the conditions of any circuit are such as to manifest self-induction, the results would be different and perhaps dangerous as compared with the conditions which existed at the time the tests were taken?

Professor W. M. Thornton (*in reply*): I am glad to hear Prof. Hay's remarks on the improvement of electrical apparatus underground. My own feeling is that the next and very difficult step is to secure a state of maintenance equal to the quality of the installation.

Mr. Statham's results are interesting as showing that he, in common I believe with Dr. Wheeler and Mr. Morgan, has worked with a type of mechanical make-and-break that might have been specially designed to mask all difference between direct- and alternating-current sparks. We found 15 years ago that a contact made so that the surfaces were scraped open at break was useless as a means of discriminating between one set of electrical conditions and another. The circuit constants, and even voltage, are then of less influence on the igniting properties of the spark than the physical or mechanical conditions of the break. A scraping contact, made by a thin spring pressing against a pole and at the point of break making a sharp flick, gives to the spark a shortness of duration comparable with the period of an alternation, so that so far as break is concerned there is no difference between the time of extinction of the two, nor has the rapidity of alternation of the current then any chance of affecting the result. Such a condition is never met in practice; breaks of cables or contacts do not occur between thin steel or brass springs. There is the further objection to mechanical breaks of this kind that the current density at the point of break is very high, and that the thermal capacity of the metal behind the break has no time to influence the spark. Everything therefore is equalized. For this reason we abandoned after a few months' research the method which appears to find most favour with these investigators.

Mechanical breaks are always troublesome. If an electromagnetic break is used, the current must be shut off before make, or the contacts chatter and ignition can occur at make. Unless a mechanical "knock-off" device is used the break is relatively slow at the moment of opening the contacts, and this again tends to equalize the effects of direct and alternating current, for the spark in an alternating-current circuit then lasts many periods and is equivalent to a direct current. In practice, breaks most usually occur, as I have found by many trials, by a sharp straight pull-out of conductors, not a slow separation or the flick of a spring. For this reason and others, in the course of a long series of trials I gave up mechanical breaks as less reliable than hand control. I found that two round conductors crossed at right angles and separated either by hand with a quick turn or by an eccentric motion having this effect, gave entirely consistent results that could be repeated within 1 per cent at the critical values, and that method has been followed consistently for some years. The fact that these investigators have failed to obtain any difference between direct and alternating current shows that their method was not suitable for discriminating between them. For in the demonstration (at the meeting) I showed that 0·7 ampere direct current gave the same ignition as over 7 amperes alternating current, the circuits, voltages and mode of break being the same. That there is a distinct difference in practice between direct- and alternating-current working in favour of the latter is borne out by Mr. Walker's remarks, and many experienced colliery electrical engineers will agree with him. I believe that small low-voltage machines could be installed, as he says, in a haulage or pump house, and supply a district with light under conditions of safety and shock much in advance of anything now in use. A method of obtaining frequencies of 150 has now been found which makes such a scheme practicable. It is to use an induction motor with specially wound poles as a frequency changer and transformer, giving at the same time a rise of frequency from, say, 50 to 150 and a fall of voltage to any desired value at the slip-rings.

In reply to Mr. Crowther, I would refer him for full particulars on direct-current bells to a paper by Dr. Wheeler and myself on "Bare Wire Signalling." Alternating-current bells are, I believe, now under investigation here.

Mr. Hunt calls attention to the many interesting scientific side-lines of this work. There is a great field for younger investigators, but it is difficult to find the combination of physical, chemical and engineering experience necessary to obtain results in the time a young or post-graduate student has available. For example, it is now practically certain that all the phenomena of spark ignition arise from the energizing of molecules of one of the two combining gases, probably in part both, by electromagnetic radiation from the spark. This introduces the large question of quantum-action, and work on these lines leads to interesting results, but to find the ultimate physical reason for the differences between direct- and alternating-current break-sparks, impulsive and condenser discharge-sparks, based on detailed experimental research on quantum lines is a great and difficult research, and there is more pressing work to hand in consolidating the advance which has been made during the last 15 years in the improvement of electrical conditions underground.

PROCEEDINGS OF THE INSTITUTION.

46TH MEETING OF THE WIRELESS SECTION, 6 MAY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 1st April, 1925, were taken as read and were confirmed and signed.

The Chairman announced that the following nominations had been made by the Wireless Section Committee to fill the vacancies which would occur on the Committee on the 30th September, 1925 :—

Chairman : Major B. Binyon, O.B.E., M.A.

Members of Committee : Mr. P. R. Coursey, B.Sc., Mr. L. B. Turner, M.A., Captain H. J. Round, M.C., and Mr. E. H. Shaughnessy, O.B.E.

A paper by Captain H. J. Round, M.C., Member, and Messrs. T. L. Eckersley, K. Tremellen and F. C. Lunnon, entitled " Report on Measurements made on Signal Strength at Great Distances during 1922 and 1923 by an Expedition sent to Australia " (see page 933), was read and discussed.

On the motion of the Chairman a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.42 p.m.

53RD ANNUAL GENERAL MEETING, 7 MAY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The notice convening the meeting was taken as read. The minutes of the Ordinary Meeting held on the 23rd April, 1925, were also taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

Messrs. G. A. Gardner and A. W. Marshall were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows :—

ELECTIONS.

Associate Members.

Bentley, John.
Church, George Henry.
Davidson, Ward Follett, M.Sc.
Duguid, David Robertson.
Gardner, Alfred Charles.
Green, Ernest Hedley R.
Hill, Thomas.
Kamm, Leo.
Lay, Francis Arthur.
McDermott, John.
Payn, Harry.
Walker, Vernon.
Ward, Cyril Alfred.

Graduates.

Bagchi, Kamakhija Prasad.
Bancroft, Herbert Douglas.
Blake, George Thomas.
Cain, Sidney John.
Clissold, William Cornelius.
Davies, Thomas Edward.
Humphreys, Herbert Frederick.
Lewis, Llewellyn Brigstocke.
Magrow, Gordon Emm.
Shepherd, David Kennedy.
Sundar, Padma Malla, B.Sc.
Walker, John.

Students.

Adney, William Stanley.
Ashdown, Herbert Arthur, B.Sc.(Eng.).
Beale, Shirley John M.
Beney, William Harry.
Birtwistle, Marshall.
Bothamley, Henry Valentine.
Clements, Vernon Arthur H.
Cooke, Edward Maurice.
Davis, John James.
Drew, Denis Arthur, B.Sc.(Eng.).
Drummond, Charles Walter B.
East, Norman.
Edmunds, Frederick William.
Edsall, Eric Arthur M.
Edwards, Herbert Carlton.
Gray, George William E.
Harmer, Leslie Brooke.
Harvey, Leonard.
Hebblethwaite, Arthur William.
Herwald, Nehemiah.
Kantebet, Shankar Rao, B.A.
Keens, John Ernest A.
Lambert, Douglas Edward.
Lee, Kent D.
McLean, Archibald Legget.
Morfitt, George Ernest.
Prior, Frederick Ernest.
Prowse, John Albert.
Ridgeway, John Whinfrey.
Roberts, Albert Victor.
Savage, John Henry.
Scott, James Stevenson.
Shepherd, Cyril.
Smith, Edwin Marshall.
Southin, Charles Frederick.
Stanley, Thomas Edward.
Tordoff, William Humphreys.
Tsao, Tsen-Cha.
Tyack, Francis George.
Verity, Ronald Meysey.
White, Thomas Sydney.
Wigan, James William.
Wilde, William Norman.
Willis, Leslie Robert K.
Winch, Richard Frederick.

TRANSFERS.

Associate Member to Member.

Bridger, William, B.Sc.(Eng.).
Davies, George Frederick.
Hunter, Egerton Baird.
Hurford, George.
Leadbeater, James.
Parkinson, Frank.

Graduate to Associate Member.

Akehurst, Arthur Gerald.
Blaquiere, Henry Arnold.
Campbell, John James B., B.Sc.
Carter, Arthur.
Chatterjee, Sarat Kumar, B.Sc.(Eng.).
Gray, Ronald, M.C.
Leyland, Arthur James, B.Sc.Tech.
Mundy, Sydney George.
Wales, William Arvon.
Wicks, Percy, B.Sc.

Student to Associate Member.

Butler, Percy, B.Sc.
Douglas, John, B.Sc.
Lee, Herbert Cleave.
Turner, Victor Robert.

Associate to Associate Member.

Grier, John James.
Webber, Wallace James.

Student to Graduate.

Alford, Ferderick Albert H.
Angier, John Ralph T.
Barrow, Lucien Leacock.
Bygott, Hugh Cecil.
Dickinson, Richard Heath.
Gibbs, William Reginald.
Newman, Claude.
Redfearn, Charles Herbert.
Rhodes, Arnold, B.Sc.Tech.
Wells, Ewart Henry, Ph.D., M.Sc.

The following lists of donations were taken as read and the thanks of the meeting were accorded to the donors :—

Library : Air Ministry; W. Aitken; C. Andry; Astronomer Royal; A. Bachellery; Professor F. Bacon, M.A.; F. G. C. Baldwin; Messrs. E. Benn, Ltd.; British Engineering Standards Association; British Engineers' Association (Incorporated); Comité International des Tables Annuelles de Chimie, de Physique et de Technologie; General Assembly, Pennsylvania; F. M. Denton; F. Deulicke; Electricity Commissioners; Government Inter-Departmental Standardization Committee; Sir Robert Hadfield, Bart., F.R.S.; K. Hedges; High Commissioner for Canada; W. S. Ibbetson; Imperial College of Science and Technology; Institution of Engineers, Australia; H. M. Lacey; H. I. Lewenz; Librairie Vuibert; Library Association; Messrs. P. Lund, Humphries & Co., Ltd.; "Locomotive, Railway Carriage and Wagon Review"; Messrs. Merz and McLellan; W. M. Mordey; J. S. C. Morris (Exor. M. Hughes); I. Namari; Lieut.-Colonel W. A. J. O'Meara, C.M.G., R.E.; Patent Office Library; Director of Posts and Telegraphs, India; Chief Electrical Engineer, Public Works Department, New Zealand; Messrs. S. Rentell & Co., Ltd.; Royal Society of Arts; Director, Royal Technical College, Glasgow; Director, Science Museum; Chief Experimental Officer, Signals Experimental Establishment, Woolwich; Messrs. E. & F. N. Spon, Ltd.; C. L. E. Stewart; S. A. Stigant; Syndics of the Cambridge University Press; Under-Secretary for Mines; University Tutorial Press, Ltd.; and Messrs. H. F. & G. Witherby.

Benevolent Fund : (See list of Donations on page 519.)

The President, after reviewing the work of the session, moved "That the Annual Report of the Council for the year 1924–25 * as presented be received and adopted."

* See page 571.

The resolution was seconded by **Mr. A. H. Allen,** and comments and suggestions were made by **Mr. F. W. Purse, Mr. L. W. Phillips, Mr. D. G. Hurlbatt,** and **Mr. P. M. Baker,** to which the President replied.

The Report was then unanimously adopted.

The chair was then vacated by the President (who had to leave the meeting in order to attend another engagement) and taken by **Mr. S. Evershed,** Vice-President.

The Chairman : I now call upon the Honorary Treasurer to move a resolution in regard to the Statement of Accounts and Balance Sheet.*

Mr. P. D. Tuckett (Hon. Treasurer) : I am happy to be able to congratulate the members on what I feel sure they will regard as a very satisfactory statement. It will be seen that in spite of the reduction in the subscriptions which came into force on the 1st January, 1924, the income for the year is only £2 094 less than in the previous year. On the other side of the Revenue Account the expenditure shows an increase of £1 090, excluding the reserve provisions at the foot of the statement. That increase of £1 090 is mainly attributable to one or two special items. Under the heading of "Institution Building" there is an increase of £900 in the amount of £1 500 reserved for Repairs. As you will see from the Balance Sheet that we have had to write off £855 against the Repairs Suspense Account, whilst the still larger amount of £1 297 was written off in the previous year, it was felt that an annual provision of £600 was hardly adequate and that it would be wise to increase it, at any rate for a time, to the larger figure of £1 500. This should result in restoring the somewhat depleted Repairs Suspense Account and should enable each year's repairs to be met by a charge against this Account, since it is most unlikely that they will on the average exceed £1 500. In addition to this increased Repairs provision, we have had to incur a very exceptional expenditure of £1 615 in providing new boilers, etc.; and there are several other small increases, including one of £394 in the amount of the Special Grants made by the Council. As a set-off against these increases you will be glad to see that we received an additional rental of £2 067 from our tenants in this building, besides saving £1 093 in the net cost of the *Journal*, thanks to increased sales and advertisements. *Science Abstracts* also, which used to make a substantial call on our resources, cost us only £68. It is true that this exceeds the previous year's figure by £41, but I think you will agree that it is still quite a moderate figure and one on which the Committee responsible for the publication are entitled to be congratulated. Of the special items at the foot of the Account, it will be seen that this year only £3 500 has been carried to the Reserve Fund for contingencies and mortgage redemption, as against £4 500 a year ago, whilst £1 310 less has been expended on furniture, fittings and apparatus. The balance of £2 925 carried to the General Fund in the Balance Sheet is thus only £1 032 smaller than the amount carried down a year ago. As stated in the Report, the Assets taken at their book values,

* See page 580.

after deducting the Liabilities, now amount to £133 016, an improvement of £7 616 over the corresponding figure a year ago. It is gratifying to have this proof of the strong financial position in which the Institution now stands, and I believe that the members have every reason to feel satisfied with it and with the prospects for the current year, although there is one heavy item of expenditure which will adversely affect this year's Accounts, and that is the re-wiring of this building. It has been found that the wiring is worn out, and the Council have decided that it must be renewed at an estimated cost of about £3 000. In addition, this is the year of the quinquennial valuation for rating purposes, and the chances are that our rates will be substantially increased. So that although I do not anticipate any marked reduction in the amount of the balance which we shall be able to carry to the General Fund at the end of the year, I doubt whether it will exceed the balance shown this year, and it is quite possible that it may be somewhat smaller. With these few remarks I beg to move : "That the Statement of Accounts and the Balance Sheet for the year ended 31st December, 1924, as presented be received and adopted."

The resolution was seconded by **Mr. J. E. Kingsbury** and after the Chairman had replied to comments by **Mr. D. G. Hurlbatt, Mr. F. W. Purse** and **Mr. E. W. Moss**, was unanimously adopted.

The following resolution, moved by **Mr. Ll. B. Atkinson** and seconded by **Mr. P. M. Baker**, was carried with acclamation : "That the best thanks of the Institution be accorded to the following officers for their valuable services during the past year: (*a*) The Hon. Secretaries of the Local Centres and Local Hon. Secretaries abroad, and (*b*) the Hon. Treasurer (Mr. P. D. Tuckett)."

Mr. A. F. Harmer then moved "That Messrs. Allen, Attfield & Co., be appointed Auditors for the year 1925–26."

The resolution was seconded by **Mr. W. Nairn** and carried unanimously.

The meeting terminated at 6.55 p.m.

47TH MEETING OF THE WIRELESS SECTION, 3 JUNE, 1925.

(Held in the Institution Lecture Theatre.)

Admiral of the Fleet Sir H. B. Jackson, R.N., G.C.B., K.C.V.O., F.R.S., took the chair at 6 p.m. in the absence of Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section.

The minutes of the meeting of the Wireless Section held on the 6th May, 1925, were taken as read and were confirmed and signed.

The Chairman reported that, no other nominations having been received to fill the vacancies which would occur on the Committee on the 30th September, 1925, the Committee's nominees* had been duly elected.

A paper by Dr. R. L. Smith-Rose, M.Sc., Member, entitled "The Effect of Wave Damping in Radio Direction-Finding" (see page 923), was read and discusssd.

On the motion of the Chairman a hearty vote of thanks was accorded to the author, and the meeting terminated at 7.25 p.m.

* See Proceedings of the meeting of the Wireless Section held on the 6th May, 1925 (page 1041).

INSTITUTION NOTES.

List of Members.

A new List of Members (corrected to the 1st September, 1925) is in preparation and members wishing to receive a copy should apply to the Secretary.

International Conference on E.H.T. Lines.

It is proposed, subject to there being a sufficient demand, to publish an English edition (in two volumes of about 1 100 pages each) of the papers read at the International Conference on E.H.T. Lines held in Paris from the 16th to the 25th June, 1925. The volumes will also contain a report of the discussions.

If the demand reaches 400 copies, the price will be £4 for the two volumes, but in the event of 800 copies being subscribed for, the price will be £2 10s.

In order that an early decision may be arrived at as to whether to publish an English edition, those wishing to subscribe for copies are requested to inform without delay

Monsieur Tribot Laspière,
Union des Syndicats de l'Électricité,
25, Boulevard Malesherbes,
Paris,

of the number of copies they will require.

A French edition of the papers and discussions will also be published, provided not less than 1 000 sets are subscribed for. The price will be 200 francs per set, but after the 1st November, 1925, the price will be increased to 250 francs. Orders for the French edition should also be sent to M. Tribot Laspière at the address given above.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 August–25 September, 1925 :—

	£	s.	d.

THE USE OF THE CATHODE-RAY TUBE AS A WATTMETER AND PHASE-DIFFERENCE MEASURER FOR HIGH-FREQUENCY ELECTRIC CURRENTS.*

By J. A. FLEMING, D.Sc., F.R.S., Honorary Member.

(*Paper received 9th December*, 1924.)

SUMMARY.

This paper contains an account of the manner in which a cathode-ray tube can be employed to measure high-frequency power, i.e. as a wattmeter, by the delineation and measurement of the ellipse formed on a phosphorescent screen by a cathode-ray spot, which is oscillated in two directions at right angles by the current and voltage of the circuit under test.

Now that the cathode-ray oscillograph with oxide-coated hot cathode has been made into an instrument capable of being operated by a few hundred volts furnished by dry cells in place of the troublesome electrostatic machine, due to the research department of the Western Electric Company, it has become a valuable appliance for high-frequency measurements. The following theorem, which has not previously been given, may therefore be found useful in connection with the use of the cathode-ray oscillograph as a wattmeter for high-frequency circuits.

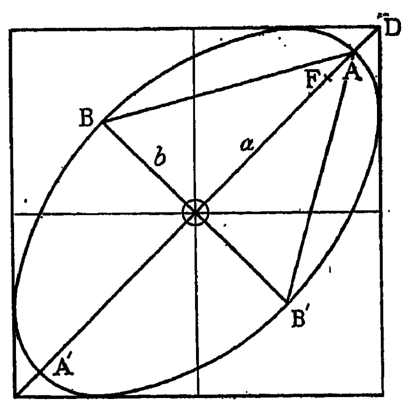
In this form of tube the cathode particles are projected along the tube and pass between two pairs of parallel deflecting plates, set with their planes at right angles. By giving to one or both of these pairs of plates a difference of potential the cathode ray, and therefore the green spot on the phosphorescent screen, can be deflected in one or both of two directions which are at right angles to each other.

Suppose one pair of plates connected to the terminals of a non-inductive resistance inserted in the circuit of a high-frequency current. Then the spot will be expanded into a green line perpendicular to the plane of the deflecting plates, and this is due to the motion of the cathode spot backwards and forwards with sinusoidal motion and amplitude proportional to the maximum value of the current. If, then, the other pair of plates are similarly connected to the ends of a resistance in another circuit in which there is a second high-frequency current of the same frequency and with a constant difference of phase, the cathode spot will be deflected in a direction at right angles to that of the other motion, and if the phase difference of the two remains constant the resultant motion will be a closed curve. By various devices, which it is unnecessary to specify, we can give to the cathode spot two sinusoidal motions at right angles, and make these motions have equal amplitudes and constant difference of phase, one due to the current in a circuit and the other to the potential difference causing that current. The form of the closed curve then described by the cathode spot, which is an ellipse, enables us to find the phase difference of the two currents, or of the current and voltage creating the two motions.

Thus if we assume one of the rectangular displacements to be expressed by the equation $x = A \sin \omega t$ and the other by $y = A \sin (\omega t + \theta)$, where A is the amplitude and θ the phase difference, it is easy to see that by the elimination of the time variable ωt we have the equation to the path of the cathode spot on the screen, which is

$$x^2 + y^2 - 2xy \cos \theta = A^2 \sin^2 \theta$$

This is the equation to an ellipse which is circumscribed by a square of side $2A$ and semi-diagonal OD $= A\sqrt{2}$. The major axis of this ellipse coincides in direction with the diagonal of the circumscribing square (see Figure).



To find the lengths of the semi-axes, major (a) and minor (b), put $x = y$ and $x\sqrt{2} = a$ in the above equation, and we obtain

$$a = (A\sqrt{2}) \cos (\tfrac{1}{2}\theta)$$

To obtain b, put $y = -x$ and $x\sqrt{2} = b$, and then

$$b = (A\sqrt{2}) \sin (\tfrac{1}{2}\theta)$$

Accordingly $b/a = \tan (\tfrac{1}{2}\theta)$ and $\theta = 2 \text{ arc tan } (b/a)$. Hence if the cathode spot is actuated by two sinusoidal motions at right angles to each other which have equal amplitude and phase difference θ, the cathode spot will delineate an ellipse and this curve can be photographed or drawn with the camera lucida from the green-line curve seen on the phosphorescent screen.

Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

To find the phase difference θ, all we have to do is to determine and draw the major and minor axes of this ellipse.

On the minor axis BB′ describe an isosceles triangle BAB′ with its apex at the extremity A of the major axis. Then the angle BAB′ ($= \theta$) is the phase difference of the two periodic motions. If F is one of the foci of this ellipse, then, if $OF = f$, we know that $a^2 - b^2 = f^2$, and hence that $f^2 = 2A^2 \cos \theta$. But $A\sqrt{2}$ is the length of the semi-diagonal OD of the circumscribing square, and hence the power factor, $\cos \theta$, is equal to $(OF)^2/(OD)^2$.

If then we have the path of the cathode spot drawn or photographed we can easily find the foci of this ellipse and draw the circumscribing square, thereby finding θ and $\cos \theta$ as above explained.

Assuming that one motion of the cathode spot is due to a high-frequency alternating current and the other rectangular motion to the voltage producing that current, we can thus find the phase difference and therefore the power taken up in the circuit. The cathode-ray tube thus becomes a high-frequency wattmeter much more easy to manage than any electrostatic form of wattmeter of the Kelvin-quadrant type.

THE CATHODE-RAY OSCILLOGRAPH.*

By A. B. Wood, D.Sc.

(*Paper received 17th September, 1924.*)

SUMMARY.

The paper draws attention to three commercial forms of cathode-ray oscillograph which may be employed in the study of very high-frequency alternating or impulsive electrical phenomena.

The behaviour of a stream of cathode rays in electrostatic and magnetic fields is first dealt with, and the penetrating power of cathode rays through matter is considered in relation to the velocity of the rays. Making use of this fundamental information, simple relations are obtained expressing the current and voltage sensitivities of cathode-ray oscillographs, the important features to be observed in the design of these instruments being indicated. The question of photographic sensitivity is also discussed, and calculations are made of the relative photographic effects produced by cathode rays of different velocities. It is shown that ordinary photographic plates or films are, in general, unsuitable for recording by means of low-velocity cathode rays. For this purpose a certain type of plate known as the Schumann plate, which is very rich in silver bromide relative to gelatine, is recommended for recording at very high speeds.

The principal features of three oscillographs, viz. the Dufour, the Western Electric and the author's, are described and a comparison is made of their relative advantages.

A few of the numerous applications of cathode-ray oscillographs are indicated, and a number of records made by each of the three types are reproduced in illustration.

I. INTRODUCTION.

The cathode-ray oscillograph, a recent development of the Braun tube, is rapidly becoming a necessity in many branches of physics and electrical engineering. During the past few years this form of oscillograph has emerged from the experimental stage and the commercial forms now produced may be looked upon as reliable laboratory instruments. For low-frequency alternating-current work the Duddell and Einthoven types of oscillograph fulfil a very useful purpose, but they fail entirely at very high frequencies (10 000 periods per sec. and upwards). Even at frequencies above 1 000 these oscillographs require the use of troublesome correction factors involving the relation between the natural period of the moving element and the impressed frequency.

The cathode-ray oscillograph, on the other hand, is equally sensitive at all frequencies from zero to the highest frequency of oscillation which is conceivable in an electrical circuit; for the cathode ray is, after all, an electron in motion and can therefore execute any oscillation which can be performed by other electrons oscillating in electrical circuits. On general grounds, therefore, it would seem reasonable to suppose that the cathode-ray oscillograph must ultimately supersede any other form of oscillograph which involves a moving element having inertia, like the mirror and strips of the Duddell galvanometer, or the fibre of the Einthoven instrument.

It is the object of this paper to draw attention to this new form of oscillograph which has already proved its worth in recording oscillations of the order 10^7 periods per sec. and in recording impulsive phenomena of extremely short duration. It is proposed also to deal with some of the fundamental features of the design of such oscillographs and to refer in particular to three types at present in use.

II. SOME PROPERTIES OF CATHODE RAYS.

The methods of producing a beam of cathode rays in a highly evacuated tube are dealt with in most

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

textbooks of electricity and require little more than a brief mention here. These rays consist essentially of electrons accelerated in a vacuum tube by application of suitable potentials, the velocity of the rays being a simple function of the potential difference applied. The electrons may be produced by collision with the molecules of gas in the tube or, alternatively, by means of a heated filament. In the latter case, which is generally employed in practice, the tube may be very highly evacuated and low voltages employed to accelerate the electrons. In the former case, where ions are produced by collision, a trace of gas is left in the vacuum tube and high voltages must be employed to excite a cathode stream of sufficient intensity. On general grounds it is usually considered preferable to employ a hot filament cathode, the alternative method, used in the original Braun tube, being somewhat unreliable and fickle. Before dealing with the design of cathode-ray oscillographs, it is essential to examine the behaviour of cathode rays in electrostatic and electromagnetic fields and to obtain an idea of the photographic action of rays of different speeds.

(*a*) *Charge, mass and velocity of cathode rays.*—The classical experiments of Sir J. J. Thomson in determining the values of e, e/m, and v for cathode rays * are well known. As we are only concerned here with the actual values of these quantities, we shall refer merely to the results of the latest determinations by more refined methods.† The following values may be accepted as reliable :—

$e = 1\cdot59 \times 10^{-20}$ electromagnetic units.
$e/m = 1\cdot772 \times 10^{7}$ electromagnetic units (for low-velocity rays).
whence $m = 10^{-27}$ gramme approximately.

The mass of a cathode particle is therefore entirely negligible when compared with the mass of the finest silvered quartz fibre obtainable (0·002 mm diameter), viz. 10^{-7} gramme per cm length.

The velocity v of the cathode ray is of course a function of the accelerating voltage V, and the following expression is a fairly accurate representation of the relation between them :—

$$v = 5\cdot95\sqrt{(V)} \times 10^{7} \text{ cm per second‡} \qquad (1)$$

where V is expressed in volts.

The kinetic energy of the cathode rays is therefore proportional to the accelerating voltage V.

(*b*) *Deflection in electrostatic fields.*—We shall consider only the simple case where the beam of cathode rays passes with uniform velocity v between two parallel plates in a direction normal to the lines of electric force (see Fig. 1). In this figure P_1P_1 and P_2P_2 represent the parallel plates of length λ at a distance d apart. A potential difference of E units is applied to the plates, and the stream of cathode rays travels initially along the line OX. In their passage through the electrostatic field, however, the negatively charged particles are deflected towards the positively charged plate. At the point of emergence from the plates the rays have been deflected a distance y_1 from the line OX and are travelling along a path inclined at an angle α to this line.

If m is the mass of the cathode particle and e its charge, then the force displacing the particle in the direction of the Y axis is $e(E/d)$ and $m(d^2y/dt^2) = eE/d$. On integrating we have

$$\frac{dy}{dt} = \frac{eE}{md}t + C_1$$

and

$$y = \frac{eE}{2md}t^2 + C_1t + C_2$$

The constants of integration vanish, since dy/dt and y are both zero when $t = 0$.

Writing $t = x/v$, we have

$$\frac{dy}{dt} = \frac{eE}{md}\cdot\frac{x}{v}$$

and

$$y = \frac{eE}{2md}\cdot\frac{x^2}{v^2}$$

That is, the rays travel along a parabolic path between the deflecting plates, the displacement y being at any instant proportional to the square of the distance x travelled by the rays from the point O.

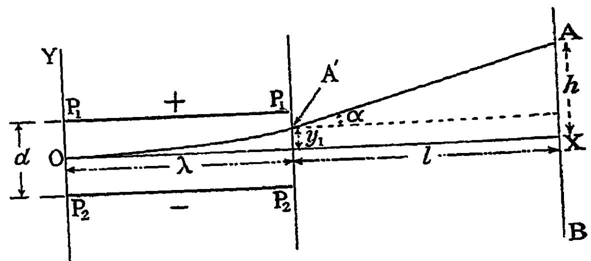


FIG. 1.

At the point where the rays emerge from the parallel plates $x = \lambda$, and the direction of the rays makes an angle α with OX at a point A′ displaced a distance y_1 at right angles to OX. After leaving the deflecting plates the rays travel along a straight line A′A until they strike the plane AB at A, the total displacement along the Y axis being AX $= h$, where $h = y_1 + l\tan\alpha$, l being the distance traversed by the rays after leaving the deflecting plates.

$$\tan\alpha = dy/dx, \quad \text{where } x = \lambda,$$

$$\therefore \tan\alpha = \frac{1}{v}\cdot\frac{dy}{dt} = \frac{eE}{md}\cdot\frac{t}{v} = \frac{eE}{md}\cdot\frac{\lambda}{v^2}$$

whence

$$h = \frac{eE\lambda^2}{2mdv^2} + \frac{eE\lambda l}{mdv^2}$$

i.e.

$$= \frac{e}{m}\cdot\frac{E}{v^2}\cdot\frac{\lambda}{d}(l + \tfrac{1}{2}\lambda) \qquad (2)$$

This relation giving the final displacement of the cathode rays is of fundamental importance in the design of a cathode-ray oscillograph and will be referred to later.

(*c*) *Deflection in magnetic fields.*—Here again we shall deal only with the simple case where the stream of cathode rays travels along a path at right angles

* See J. J. THOMSON: "Conduction of Electricity Through Gases."
† See MILLIKAN: "The Electron."
‡ See G. W. C. KAYE: "X-rays."

to the lines of magnetic force. The deflection produced under these conditions will be at right angles to the path of the rays and to the magnetic field. Thus, in Fig. 1, $P_1P_1P_2P_2$ is the pole face, the magnetic lines being at right angles to this plane. In this case the cathode ray, a charge e moving with velocity v, behaves like a current element ev in a magnetic field of strength H. The path of the ray is a circle of radius of curvature ρ. The force acting on the ray is Hev, and we have therefore

$$mv^2/\rho = Hev$$

or

$$H\rho = mv/e$$

In Fig. 1,

$$2\rho y_1 = \lambda^2 \text{ (approximately for a circular path)}$$

i.e.

$$y_1 = \frac{eH}{2mv}\lambda^2$$

or at any point on the path of the ray

$$y = \frac{eH}{2mv}x^2 \quad \text{and} \quad \frac{dy}{dx} = \frac{eH}{mv}x$$

At the point A′, where $x = \lambda$ and $y = y_1$, when the rays leave the magnetic field

$$y_1 = \frac{eH}{2mv}\lambda^2 \quad \text{and} \quad \tan\alpha = \frac{dy}{dx} = \frac{eH}{mv}\lambda \text{ (when } x = \lambda)$$

Hence

$$h = l\tan\alpha + y_1$$
$$= \frac{eH\lambda l}{mv} + \frac{eH}{2mv}\lambda_1^2$$

i.e.

$$h = H\frac{e}{mv}\lambda(l + \tfrac{1}{2}\lambda) \quad . \quad . \quad . \quad . \quad (3)$$

which is another fundamental relation for oscillograph design.

(*d*) *Penetrating power*.—Lenard (*Wied Annalen*, 1895) showed that for fast-moving cathode rays the extent of absorption in different substances is roughly proportional to the density. The penetrating power of the cathode ray varies very greatly with its speed. The highest-speed rays (10^{10} cm per sec.) can only penetrate 2 or 3 mm of air at normal temperature and pressure.

It has been shown theoretically by Sir J. J. Thomson, and confirmed experimentally by Whiddington * and others,† that the loss of velocity of cathode rays in passing through matter is expressed by the relation

$$v_i^4 - v_e^4 = ad \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where v_i is the velocity with which the rays impinge on the absorbing layer, and v_e is the velocity of emergence after passing through a thickness d; a is a constant depending on the density of the absorber (e.g. Whiddington gives a as equal to 2×10^{40} for air, 732×10^{40} for aluminium, $2\,540 \times 10^{40}$ for gold, whilst Terrill states that $a = 5 \cdot 05 \times 10^{42}\rho$, where ρ is the density of the material).

The above relation (4) gives us a simple expression for the maximum depth of penetration of rays of velocity v into a layer of solid matter. In this case $v_e = 0$ and $d = t$, the maximum thickness of matter penetrated.

Thus

$$t = v^4/a \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

the maximum thickness t varying directly as the fourth power of the velocity of the cathode rays and approximately inversely as the density of the absorbing layer.

In Equation (1) above, it is shown that the velocity of the cathode rays is proportional to the square root of the accelerating voltage V; hence we may write Equation (5) in the form

$$t = kV^2/a \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

i.e. the thickness of layer penetrated is proportional to the square of the voltage generating the cathode rays.

III. Voltage, Current and Photographic Sensitivity of Cathode-Ray Oscillographs.

By making use of the fundamental relations (1) to (6) obtained in Section II, we are enabled to design a cathode-ray oscillograph to fulfil any desired conditions of voltage, current or photographic sensitivity.

(*a*) *Voltage sensitivity*.—It will be seen, from consideration of Equation (2) above, that the final deflection h of a beam of cathode rays after passing through an electrostatic field of strength E/d and length λ is directly proportional to the potential difference E applied to the deflecting plates, inversely proportional to v^2, and directly proportional to a constant involving the dimensions of the deflecting plates. The value of h given by Equation (2) may be considerably simplified if we introduce the actual values of some of the constants involved. Thus we may substitute for v the value given in Equation (1), viz. $V = 5 \cdot 95\sqrt{(V)} \times 10^7$ cm per sec., and for e/m the constant $1 \cdot 772 \times 10^7$ electromagnetic units or $5 \cdot 316 \times 10^{17}$ electrostatic units. In this manner the expression for h reduces to

$$h = 0 \cdot 50\ EK/V \text{ cm}$$

where E the potential difference across the deflecting plates, and V the potential difference generating the cathode rays, are both expressed in volts; and $K = (\lambda/d)\,(l + \tfrac{1}{2}\lambda)$, the voltage constant of the oscillograph, depends on the dimensions of the oscillograph.

The voltage sensitivity of the oscillograph is therefore given by

$$\frac{K}{2V} \text{ cm per volt} \quad \text{or} \quad \frac{2V}{K} \text{ volts per cm} \quad . \quad (7)$$

This expression holds good for any design of cathode-ray oscillograph using parallel deflecting plates. It will be seen that the sensitivity (expressed in cm per volt) can be increased by (*a*) decreasing V, the voltage generating the rays, or (*b*) increasing K, the oscillograph "voltage constant."

K can be increased by increasing l and λ (the length of the plates) or by decreasing d (the distance apart of the plates). There are, of course, practical limits to the oscillograph constant.

For example, in one of the oscillographs used by the author, $\lambda = 8$ cm, $d = 1$ cm, and $l = 16$ cm

* R. Whiddington: *Proceedings of the Royal Society*, A, 1911–12, vol. 86, p. 370.

† B. F. J. Schonland: *ibid.*, A, 1923, vol. 104, p. 235; and H. M. Terrill: *Physical Review*, 1923, vol. 22, p. 101.

approximately; i.e. $K = 160$ whence $h = 80/V$ cm per volt, or the sensitivity expressed in volts per cm deflection is equal to $V/80$. For a voltage $V = 3\,000$ generating the cathode rays the sensitivity is 37·5 volts per cm, which is in good agreement with that actually observed. With an accelerating voltage of only 300 volts the sensitivity would be increased ten-fold, i.e. to 3·75 volts per cm. It is evident from (7) above that by suitably choosing (*a*) the voltage V producing the cathode rays, and (*b*) the dimensions of the deflecting plates and the distance from the screen, a very wide range of voltage sensitivity can be obtained. Under certain circumstances, to which we shall refer later, the minimum value of V is limited, in which case increased sensitiveness can be obtained only by method (*b*).

(*b*) *Current sensitivity*.—The effect of a current on the cathode stream is of course dependent on the magnetic field which it produces. The extent of deflection of the cathode rays by a magnetic field is indicated by Equation (3) above, where it is shown that the deflection obtained is directly proportional to the strength of the magnetic field (and hence to the current exciting the magnet) and inversely proportional to the velocity of the cathode rays. The deflection is also proportional to a constant involving the dimensions and distance apart of the magnet poles, and to their distance from the photographic plate or phosphorescent screen.

By substituting the values $e/m = 1\cdot772 \times 10^7$ electromagnetic units and $v = 5\cdot95\sqrt{(V)} \times 10^7$ cm per sec. in Equation (3) we find

$$h = 0\cdot298\frac{H}{\sqrt{V}}\lambda(l + \tfrac{1}{2}\lambda)$$

This expression implies that the magnetic sensitivity of the oscillograph is

$$\left.\begin{array}{ll} & \dfrac{3\cdot36\sqrt{V}}{\lambda(l + \frac{1}{2}\lambda)} \text{ gauss per cm deflection} \\ \text{or} & \dfrac{0\cdot298\lambda(l + \frac{1}{2}\lambda)}{\sqrt{V}} \text{ cm deflection per gauss field strength} \end{array}\right\} \quad (8)$$

It is more convenient, however, to express sensitivity in terms of current strength or ampere-turns. Consider a magnet of N turns wound on a laminated iron core with a large air-gap * of length d, the length of the pole-face being λ in the direction of the cathode stream. The strength of the magnetic field in the air-gap is given by

$$H = \frac{4\pi NI}{10d}, \text{ where } I \text{ is the current in amperes.}$$

Hence we may write for the deflection of the cathode rays

$$h = 0\cdot298\frac{4\pi NI\lambda}{10d\sqrt{V}}(l + \tfrac{1}{2}\lambda)$$

or

$$h = \frac{0\cdot375K'}{\sqrt{V}}NI$$

where K' is the "current constant" * of the oscillograph and is equal to $(\lambda/d)(l + \frac{1}{2}\lambda)$. The current sensitivity of the oscillograph is therefore given by

$$\left.\begin{array}{ll} & 0\cdot375K'/\sqrt{V} \text{ cm per ampere-turn} \\ \text{or} & 2\cdot67\sqrt{(V)}/K' \text{ ampere-turns per cm deflection} \end{array}\right\} \quad (9)$$

The values of magnetic sensitivity (8) apply to all cathode-ray oscillographs, whether the magnetic fields are produced by iron-cored magnets with large air-gaps or by solenoidal coils with air cores.

The current sensitivity (measured in cm per ampere-turn) is increased by:—

(*a*) Decreasing the voltage V generating the rays.
(*b*) Increasing K' the "current constant" of the oscillograph. K' can be increased by increasing the length λ of the magnet or by decreasing the gap d, or by increasing the distance l from the magnet to the screen or photographic plate.

For example, in an oscillograph now in use, $\lambda = 1\cdot8$ cm, $d = 1\cdot8$ cm, $l = 16$ cm approximately, whence $K' = 16\cdot9$. Consequently $h = 6\cdot35/\sqrt{V}$ cm per ampere-turn. With a magnet of 700 turns a current of 0·03 ampere produces a deflection of 2·5 cm approximately when the voltage V accelerating the cathode rays is 3 000. The calculated value of h is $\frac{6\cdot35}{\sqrt{3\,000}} \times 700 \times 0\cdot03$ cm, i.e. 2·44 cm, which is in good agreement with the observation.

It will be noticed that the current sensitivity of the oscillograph is inversely proportional to $\sqrt{V}$, i.e. to v, or to the momentum of the rays; whereas the voltage sensitivity was shown to vary inversely as V, i.e. as v^2, or as the kinetic energy of the rays.

(*c*) *Photographic sensitivity*.—It is well known that cathode rays when they fall on a screen of phosphorescent material, e.g. willemite or calcium tungstate, produce visible luminous effects. In a similar manner when these rays strike the emulsion of a sensitive photographic plate a blackening effect (after development) is produced. These phosphorescent and photographic effects depend, as one would anticipate, on the velocity of the cathode rays. The higher the velocity of the rays the greater is the energy available and the greater is their power of penetration into the phosphorescent material or the photographic film. It was shown in Section II(*d*) that the maximum depth of penetration t of a cathode ray into a layer of matter is proportional to the fourth power of its velocity v (i.e. to the square of the exciting voltage V) and approximately inversely as the density of the absorbing layer. Thus $t = v^4/a$ cm, where a is a constant depending on the absorbing material.

The ordinary photographic film consists of an emulsion of silver bromide in gelatine. When cathode rays fall on such a layer their energy is rapidly absorbed by numerous collisions with the molecules of gelatine and silver bromide. The value of the constant a in

* The reluctance of the air-gap is here considered to be very large compared with that of the iron circuit. The same line of argument applies also to any air-core solenoid used to deflect the cathode rays.

* It should be observed that the oscillograph constants K and K' refer to voltage and current deflections respectively; they are entirely independent constants.

this case is estimated to be 10^{43} for an ordinary gelatine emulsion plate ($\Delta = 2\cdot0$) whence

$$t = v^4 \times 10^{-43} \text{ cm approximately.}$$

Combining this with Equation (1), which gives the velocity v in terms of generating voltage V,

$$t = 1\cdot25 V^2 \times 10^{-12} \text{ cm approximately,}$$

giving the thickness t in cm which cathode rays of any voltage V can penetrate into a photographic film.

Now the thickness of the film on an ordinary photographic plate is approximately 10^{-3} cm; hence we can calculate the percentage depth of penetration of rays of different velocities into this film.

V, in volts	t, in cm	Percentage thickness of film penetrated
30 000	$1\cdot1 \times 10^{-3}$	100 (complete penetration)
3 000	$1\cdot1 \times 10^{-5}$	1
300	$1\cdot1 \times 10^{-7}$	0·01

It will be seen from the table that high-velocity cathode rays (30 000 volts) can penetrate completely an ordinary photographic layer, and may therefore be expected to have a very efficient photographic action. Lower-velocity (e.g. 3 000 volts) rays, however, can only penetrate a very small depth, 1 per cent of the film, the photographic effect in this case being superficial only, since the rays never reach the lower layers of sensitive silver-bromide granules. As the velocity is still further diminished, e.g. with 300-volt rays, the depth of penetration is practically zero and the photographic effect is negligible in comparison with that of the higher-velocity rays.

In a previous paper by the author * methods of increasing photographic sensitivity were described. The first of these methods consists in increasing the proportion of silver bromide to gelatine in the emulsion. Thus in the emulsion of an ordinary gelatine plate the relative proportion of silver bromide to gelatine is approximately 0·88 by weight and 0·174 by volume, whereas in a special form of Schumann plate made by Hilgers the proportion is 90 by weight and 18·2 by volume.† That is, for equal volumes of the film in Schumann and ordinary gelatine plates, the former contains 100 times as much silver bromide as the latter. The density of the film is thereby increased 3 times, but the chance of collision between cathode particles and AgBr molecules is increased 100 times. On these grounds, therefore, it would seem probable that the photographic effect produced by low-velocity cathode rays (i.e. rays which do not completely penetrate the film) is about 33 times greater in the Schumann plate than in an ordinary plate. Using these plates, good photographic effects have been obtained with rays of a velocity as low as that corresponding to 1 000 volts; below this velocity, however, the photographic effects are relatively feeble.

* *Proceedings of the Physical Society of London*, 1923, vol. 35, p. 109.
† I am indebted to Mr. A. G. Milligan, B.Sc., for the careful determination of these quantities.

The second method of increasing photographic sensitivity employs an admixture of phosphorescent material (e.g. calcium tungstate) with the photographic emulsion, or the use of a thin layer deposited on the emulsion.* The photographic effect is now due to two causes: (1) The direct effect of the cathode rays, and (2) the indirect luminous effect of the phosphorescent material in close contact with the sensitive granules.

The two methods just mentioned of increasing photographic sensitivity have proved very successful in practice and have considerably extended the possibilities of the low-voltage type of cathode oscillograph. In spite of such improvements, however, it must be realized that with diminishing velocity of cathode rays the photographic difficulties rapidly increase.

IV. Recent Commercial Forms of Cathode-Ray Oscillograph.

At the present time there are three distinct types of cathode-ray oscillograph which may be regarded as having reached the commercial stage, i.e. the stage at which they are conveniently reproducible and are likely to prove serviceable instruments in physical and electrical engineering laboratories. The first of these oscillographs is the high-voltage type designed by Monsieur A. Dufour † and operating at 60 000 volts or thereabouts. The second type is one originally proposed by Sir J. J. Thomson and developed to its present commercial form by the author.‡ This oscillograph operates on a voltage of the order of 3 000 volts. The third type, due to the Western Electric Co.,§ operates on 300 volts, but unlike the other oscillographs just mentioned can only be used for visual observations, no provision being made for photography.||

All these oscillographs employ the fundamental principles of the Braun tube, comprising essentially an evacuated vessel with means for producing a narrow pencil of cathode rays, electrostatic deflecting plates, magnetic field, and phosphorescent screen. In the Dufour oscillograph and that designed by the author, provision is made for a number of photographic plates in the vacuum chamber, and special circuits (electromagnetic and electrostatic) are employed to traverse the spot at known speeds across the plate.

(*a*) *High-voltage oscillograph.*—This instrument has been brought to a high degree of efficiency by Monsieur A. Dufour. A diagrammatic view ¶ of his oscillograph is shown in Fig. 2. As in the original form of Braun tube, the cathode rays are produced in a soft vacuum, a voltage of 60 000 being employed to accelerate the negative electrons initially in the tube and to produce others by collision. The cathode is a concave disc of aluminium "e." The beam of cathode rays is reduced to a fine

* In the latter case the phosphorescent material is washed off on development of the plate.

¶ Taken from Dufour's paper, *loc. cit.*

pencil of rays by means of a diaphragm "f" which, connected to the metal body of the oscillograph, forms the anode. Outside the tube, near "v," suitable electrostatic deflecting plates and electromagnets are arranged in accordance with experimental requirements. After passing through these electrostatic and magnetic fields the cathode rays enter the camera chamber "a" where they strike the cylindrical photographic film "g" or the glass plates "h." When a film is used the cylindrical drum supporting it can be rotated by means of an external magnetic device "p" controlling the spindle "n" through the glass cap "o."

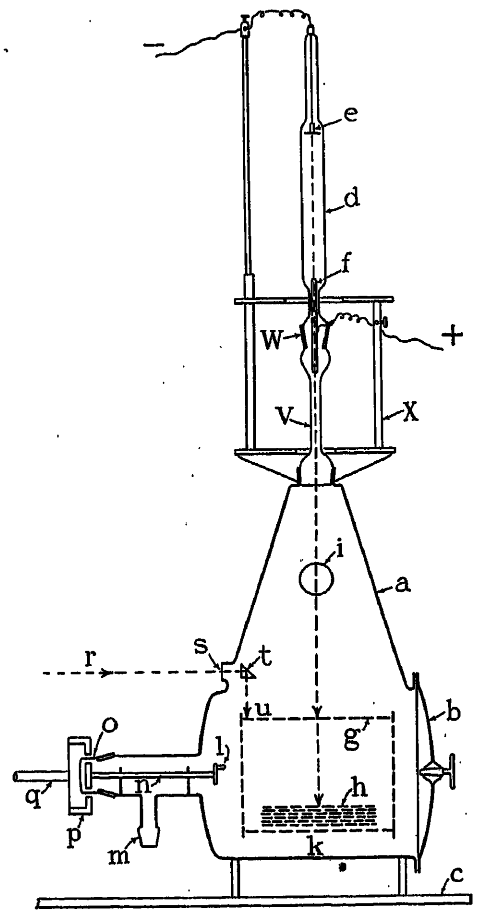

FIG. 2.

In this case a time scale can be optically recorded on the edge of the film by way of the window "s" and totally reflecting prism "t." The side "b" of the camera chamber is removable. A vessel "k" containing P_2O_5 is fitted inside the camera to absorb water vapour, which is emitted in the vacuum from the gelatine emulsion of the film or plate. The rotating drum and film are only used in low-frequency work. At very high frequencies the drum is removed and a pile of photographic plates "h" substituted. The cathode rays are in this case deflected at a known speed across the plate by means of an electromagnet in which the current is increasing at a known rate. The speeds of deflection possible by such methods are far greater than any mechanical speeds conceivable with the rotating drum.

With this oscillograph Dufour has obtained beautiful records of high-frequency alternating-current effects and impulsive or "transient" phenomena. He has employed the oscillograph most successfully in recording wave-forms of high-frequency wireless oscillations up to a frequency of 200 million periods per second, i.e. corresponding to a wave-length of 1·5 metres. The actual velocity of the cathode-ray spot in making such a record is approximately 4×10^8 cm per second. It will be realized from this fact that the photographic effect of the high-voltage cathode ray is very intense.

As we have seen in Section III (*c*), the photographic sensitivity of a 60 000-volt oscillograph is very great, for the rays attain a sufficiently high velocity to penetrate any ordinary photographic film. On the other hand, the electrostatic and current sensitivities of this type of oscillograph are correspondingly low. Dufour does not refer in his paper to the dimensions of the electrostatic deflecting plates or the magnet coils, but he states that the voltage sensitivity of his oscillograph is 100 volts per cm, whilst the current sensitivity is 10 ampere-turns per cm. Using Equations (7) and (9) given above for the voltage and current sensitivity respectively, we find that the voltage and current constants of his oscillograph are $K = 1\,200$ and $K' = 68$ respectively. These values are of course dependent on λ, d and l for the electrostatic plates and magnetic circuit. In making comparisons of the sensitivity, the values of the constants K and K' should be taken as the same in both cases. This point will be referred to later under (*d*).

It has already been pointed out that the Dufour oscillograph employs a soft vacuum, i.e. the apparatus contains sufficient residual gas to permit of production of ions by collision. Now the pencil of cathode rays as it passes between the deflecting plates ionizes this residual gas to some extent, and the space between the deflecting plates becomes conducting. If the plates themselves were included inside the vacuum chamber this leakage from one plate to the other would preclude, or at any rate impair, the use of the oscillograph for the accurate recording of certain types of electrostatic voltage effects. Dufour attempts to avoid this difficulty by fitting the deflecting plates outside the vacuum tube. The insulation between the plates is in this case practically perfect, but the space charge in the deflecting chamber is still an objectionable feature.

(*b*) *Medium-voltage oscillograph.*—An oscillograph of this type was first proposed by Sir J. J. Thomson.* Since that time the original apparatus has been considerably modified in design, particularly with a view to improving its mechanical construction and robustness and to the production of a form of instrument † which should be of general service in a laboratory. Considerable improvements have also been made in the photographic arrangements.

Strictly speaking, it would be more correct to refer to this form of oscillograph as the low-voltage type, for it has been designed to operate on a minimum

* J. J. THOMSON: *Engineering*, 1919, vol. 107, p. 543; and D. A. KEYS *Philosophical Magazine*, 1921, vol. 42, p. 473.

† A. B. WOOD, *loc. cit.*

voltage consistent with good photographic results at high speeds. It has been shown in Section III (c) that the photographic effect produced by cathode rays falls off rapidly as the voltage of the rays is decreased, and it becomes more and more difficult to obtain good photographic sensitivity as the voltage is reduced. It has been found experimentally by the author that cathode rays of voltage less than 1 000 are very weak photographically, and until improved methods of focusing these low-voltage rays, or of increasing their penetrating power,* have been devised it is not probable that an oscillograph can be designed to operate on voltages much lower than this. The normal voltage of operation of the oscillograph is 3 000 volts, the cathode rays in this case giving excellent photographic records at high speeds under suitable photographic conditions. A diagrammatic section of one form of this oscillograph is shown in Fig. 3.* A more recent form, mounted in cabinet, is shown in Fig. 4. It will be seen that the oscillograph is of very robust construction, consisting almost entirely of metal parts fitted together in such a manner that any part can easily be removed and replaced, or modified to suit the particular circumstances under which it is required. The more important parts of the instrument are fitted together and rendered airtight by means of greased conical joints. Thus it will be seen from Fig. 3 that the filament holder, the bulb, the deflecting tube, the various pumping connections and plugs operating the camera can be taken apart and refitted in a few seconds. This feature of the oscillograph is a great convenience in the laboratory. The base of the oscillograph is a heavy brass casting containing the camera and supporting the brass cylindrical deflecting tube which, in turn, supports the bulb and filament holder. The latter is constructed so that the position of the filament in the bulb, i.e. its distance from the anode, is adjustable. A burnt-out or defective filament can be replaced immediately by unscrewing it from the filament holder and fitting a new one—the same operation as fitting a new bulb to a flash-lamp. The filament itself is a flat spiral of tungsten or lime-coated platinum wire heated by a local insulated 4-volt battery and connected to the negative of the 3 000-volt supply. As in the Coolidge X-ray tube the spiral is surrounded by a metal sheath which exerts a focusing

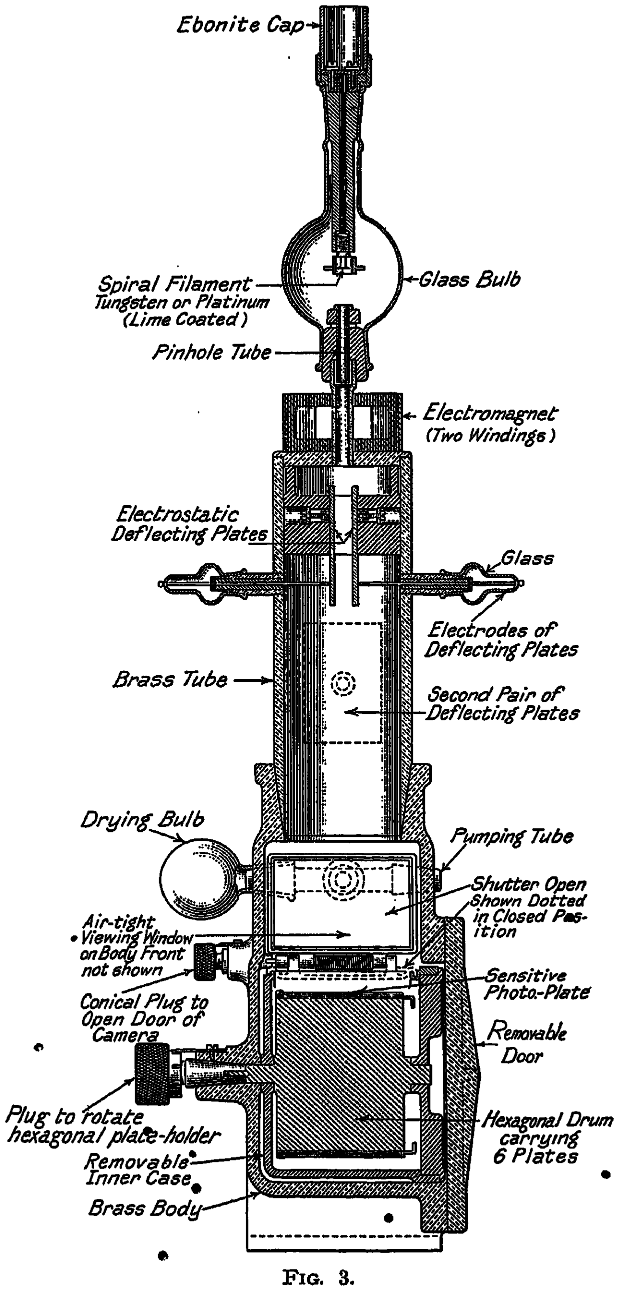

Fig. 3.

* These oscillographs are now manufactured by Messrs. H. Tinsley & Co., South Norwood.

action on the cathode beam. The latter travels towards the pinhole tube—two thin metal diaphragms about 3 in. apart and pierced by small holes about 5 or 10 mils diameter—this forming part of the anode with the metal body of the oscillograph, which is earthed.

After leaving the pinhole tube the narrow pencil of cathode rays enters the deflecting tube where it passes between two pairs of electrostatic deflecting plates, mutually at right angles, and the poles of an electromagnet. The latter may or may not contain iron in the circuit, according to the purposes for which it is required. The deflecting plates are suitably insulated and fixed in position and are connected to terminals outside the oscillograph through air-tight fittings (glass cones in Fig. 3).

After leaving the deflecting tube the rays enter the camera chamber, where they ultimately strike the door of the camera. This door is coated on its upper surface with phosphorescent material—calcium tungstate or willemite—which can be viewed through a window fitted in front of the body of the oscillograph. When a photographic record is required the door of the camera, and hence the observing screen, are removed by turning a conical plug on the side of the instrument. This exposes one of six plates fitted on a hexagonal block, which can be turned from outside as desired by means of another conical plug (see Fig. 3). By means of a hinged cover plate, light is prevented from entering through the viewing window when an exposure is being made. The hexagon with its six plates is mounted inside a light-tight casing, which can be removed from the oscillograph in broad daylight, the plates being subsequently dealt with in a dark-room.

The vacuum can be obtained by means of any of the standard high-vacuum pumps at present on the market. With an ordinary Gaede mercury pump, and a backing pump (reducing to about 1 mm pressure) the desired vacuum can be obtained in about 15 minutes, starting at atmospheric pressure. It is of course essential, unless vapour pumps are used, that suitable drying material (e.g. P_2O_5) be used to absorb water vapour. When using the oscillograph it is customary to maintain the pump connection, but this is not always necessary when a good vacuum has been reached and the filament is free from gas.

It was pointed out in Section III (*c*) that low-voltage cathode rays can only penetrate thin films of matter (of the order 10^5 cm) and that special photographic plates, Schumann plates * having a large proportion of silver granules and a minimum of gelatine, give much better results than ordinary gelatine-coated plates with a smaller proportion of silver. For high-speed records with 3 000-volt rays Schumann plates have proved far superior to ordinary plates. For comparatively low-frequency records (1 000 to 10 000 periods per sec.), however, Paget half-tone plates † have given moderately good results. The lower the voltage employed to generate the cathode rays the more necessary it becomes to employ Schumann plates.

As in the Dufour oscillograph, the cathode-ray stream is traversed across the photographic plate by electrostatic or electromagnetic methods, the rate of traverse depending entirely on the time constant of the condenser or inductance circuit respectively. These methods, giving an approximately linear time scale, have proved satisfactory up to the very highest speeds —far in excess of what is possible by ordinary mechanical methods of driving a moving film. At lower speeds other methods, as, for example, the rotating potentiometer method,* etc., may be employed. By such means the time for the cathode spot to cross the plate may easily be varied from 1 sec. to 10^{-6} sec.

In making a photographic record of an alternating-current wave-form, e.g. at 10 000 periods per sec., the rate of traverse of the spot is previously adjusted by observation of the phosphorescent screen. The procedure is briefly as follows (see Fig. 5). A steady current is passed through winding A of the electromagnet and adjusted until the spot is deflected from position (1) to position (2) off the left-hand edge of the screen.† The alternating voltage, of which the waveform is required, is then applied to one pair of electrostatic deflecting plates, thus causing the spot to oscillate along a line (3) at right angles to the direction of magnetic deflection. On closing the circuit through winding B of the magnet, which is more powerful than,

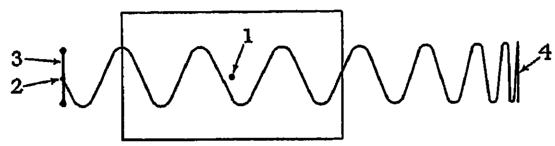

FIG. 5.

and in opposition to, winding A, the spot crosses the plate from its first position (3) on the left to another position (4) well away on the right, and, in doing so, leaves a trace of the wave-form to be recorded. The speed of traverse can be varied by varying the voltage, inductance and resistance in the circuit of B winding.

These operations, illustrated diagrammatically in Fig. 5, are first carried out visually on the phosphorescent screen, the final record being made on the photographic plate. For very high speeds of traverse it is advantageous to use the two pairs of electrostatic deflecting plates, following a procedure on similar lines to that just outlined. In this case, of course, the traverse of the spot is produced by the voltage-rise across a condenser in series with a resistance. The initial deflection of the spot to the left may, as before, be obtained by means of the electromagnet or, alternatively, by means of a steady voltage applied to the deflecting plates.

By these methods good records have been obtained of very high-speed alternating and impulsive or transient electrical effects. Reference will be made to the applications of the oscillograph in a later section of the paper.

Since this type of oscillograph employs a hot cathode of tungsten or lime-coated platinum, the vacuum is

* Supplied by Hilgers, Ltd., Camden Town.
† These plates were recommended to me by Sir J. J. Thomson.

† The spot can still be observed under these conditions by coating the body of the camera at this place with phosphorescent material.

hard and there is no tendency for the cathode stream, as it passes between the deflecting plates, to produce ionization and thereby render the space between the deflecting plates conducting. It is this feature which makes the oscillograph especially suitable for recording electrostatic changes where only small quantities of charge are involved. Slight leakage between the plates would, under such circumstances, prove fatal to the accurate recording of voltage changes.

(c) *Low-voltage oscillograph.*—A description of this instrument is given in the *Physical Review* for August 1923 by J. B. Johnson, and the tube is manufactured and supplied by the Western Electric Co. As has already been stated, the tube is only suitable for visual observations, and cannot therefore be described as an oscillograph in the same sense that the description applies to the Duddell and Einthoven instruments and to the types (a) and (b) of cathode-ray oscillographs described above. In these instruments a permanent photographic record of a wave-form or of any electrical disturbance can be obtained by a single traverse of the spot (light or cathode rays) across the photographic plate. With the Western Electric instrument, however, no provision is made for photography other than that provided in the original form of Braun tube. The Western Electric tube, however, operates on a low accelerating voltage, resulting in increased sensitivity and in diminished cost of accessory apparatus. The high-voltage generator and vacuum pumps are not required, for the tube operates on 300 volts and is evacuated at the works and sealed off permanently. The design is extremely simple, the filament (thoriated tungsten), pinhole tube anode, and two pairs of deflecting plates all being carried on a simple mounting at one end of the tube, a phosphorescent screen forming the other end. By means of a special construction of filament shield and by controlling the filament current the beam of cathode rays is focused on the screen. This focusing action is ascribed by H. J. van der Bijl and J. B. Johnson to the difference in mobility of the positive and negative electrons in the residual gas in the tube. Some of the cathode rays in passing through the residual gas produce ionization. Both the colliding electrons (the cathode rays) and the secondary electrons leave the beam, but the heavy positive electrons drift out of the beam much more slowly. Consequently the positive electrons accumulate in the path of the cathode rays and tend to pull the negative electrons (the cathode rays) inwards, with the result that they are brought to a focus. When the filament current is increased, the total positive ionization of the beam increases, the field around the beam becomes stronger, and the electrons are brought to a focus at a shorter distance. The focusing of the beam on the phosphorescent screen is therefore brought about by control of the filament current. The life of the filament is stated by the makers to be 200 hours. When a filament is burnt out it is necessary to obtain a complete new tube.

The Western Electric cathode-ray tube is mainly suitable for the examination of alternating-current phenomena reproduced on the screen in the form of Lissajous figures. The tube has been used, however, for the visual examination of transient electrical effects,* but it is not particularly suitable for this purpose, especially if the effects are of very short duration.

On account of the presence of gas in the tube, the oscillograph is quite unsuited for the examination of transient electrostatic effects where a small electrostatic charge varying with time is to be indicated by a deflection of the cathode beam. The makers claim that the tube may be used in the examination of explosion pressures by the aid of a piezo-electric crystal,† but this is not the case. For such a purpose it is essential that the leakage current between the electrostatic deflecting plates be negligible [as is the case with types (a) and (b) oscillographs described above]. The ionization between the deflecting plates of the Western Electric tube is, however, considerable and leakage currents are serious, thus rendering the tube unsuited for examination of transient electrostatic effects. In cases where the power available is unlimited this difficulty of course does not arise.

The electrostatic and current sensitivity of the low-voltage tube are of course very great, but, as we have already seen, the photographic sensitivity is correspondingly small.

Photographs of Lissajous figures or other repetition phenomena can be obtained indirectly by means of an auxiliary camera focused on the phosphorescent screen. Transient or impulsive electrical effects of an irregular or non-periodic character cannot be photographed with the oscillograph in its present form.

(d) *Comparison of the three types.*—It is proposed in this Section briefly to summarize the principal features of the three types of cathode-ray oscillograph described above. For the purpose of comparison we shall consider type (a) to be operated at 30 000 volts, type (b) at 3 000 volts, and type (c) at 300 volts, although it will be clear that in all the types the voltage may be varied in practice over a considerable range.

(i) *Electrostatic sensitivity.*—This we have seen in Section III (a) to be inversely proportional to the operating voltage V. Hence if we take the sensitivity to be unity in the 30 000-volt instrument, it will be 10 and 100 in the 3 000- and 300-volt tubes respectively, other conditions (i.e. dimensions of tube and deflecting plates) remaining the same in the three cases.

(ii) *Magnetic or current sensitivity.*—In this case [see also Section III (b)] we find the sensitivity to be inversely proportional to $\sqrt{V}$, i.e. the 30 000-, 3 000- and 300-volt types have the relative sensitivities 1, 3·16 and 10 respectively.

(iii) *Photographic sensitivity.*—It has been shown [see Section III (c)] that the depth of penetration of the cathode rays is proportional to the square of the operating voltage. Apart from other considerations, therefore, it seems reasonable to suppose that the photographic action will be determined by V^2. Hence the relative photographic sensitivities might be expected to be roughly proportional to 1, 10^{-2} and 10^{-4} respectively for cathode rays of voltages 30 000, 3 000 and 300. Unless auxiliary means are provided ‡ for

* R. A. Watson Watt: *Wireless World and Radio Review*, 1923, vol. 12, p. 600.
† D. A. Keys *loc. cit.*
‡ For example as indicated in the footnote on page 1052.

increasing the photographic action of low-velocity rays, it seems improbable, therefore, that a cathode-ray oscillograph of voltage much lower than 1 000 will be forthcoming.

(iv) *General.*—From the point of view of cheapness, convenience, and simplicity of operation, the Western Electric 300-volt tube is of course in the forefront. It is a very useful instrument for laboratory testing purposes where rough visual observations are all that is required. An oscillograph, to be of real value to the engineer and physicist, must, however, be capable of giving permanent photographic records of high-frequency effects, in a manner similar to that in which the Duddell and Einthoven instruments are used to record low-frequency phenomena. It is in this important feature that the 30 000-volt and 3 000-volt oscillographs are so valuable. These oscillographs can record wireless frequencies (of the order 10^6 periods per sec.) in a single traverse across the photographic plate. Sensitivity can be increased by means suggested earlier in the paper, and it is confidently anticipated that in this particular they can easily be brought to the require-

(2) Damped oscillations 150 × 10^6 frequency (wave-length = 2 metres).

ment of general practice. When compared with Duddell and Einthoven oscillographs, the cathode-ray type is obviously lacking in one important feature, viz. that of a multiple recording system, by means of which voltage and current characteristics may be recorded simultaneously. The future will doubtless provide means of generating two or possibly more cathode-ray streams falling on the same plate and actuated by voltage and current independently. In the meantime, however, we must make the most of the very valuable instruments at present available for recording frequencies and impulsive electrical effects which were a short time ago quite outside the range of laboratory oscillographs.

V. APPLICATIONS.

The applications of cathode-ray oscillographs are almost infinite in number and variety. On account of their fundamental property of recording faithfully any electrical effect whatsoever without distortion, they can be employed over a range of frequency from zero to as high as is conceivable in an electrical circuit. Dufour has used his high-voltage oscillograph to record frequencies varying from zero to 10^8 periods per second.

The 3 000-volt oscillograph (using Schumann plates)

MEASUREMENTS IN ELECTRICAL ENGINEERING BY MEANS OF CATHODE RAYS.*

By Professor J. T. MACGREGOR-MORRIS, Member, and R. MINES, B.Sc., Student.

(*Paper first received 22nd September, 1924, and in final form 23rd May, 1925.*)

SUMMARY.

This paper is intended as a survey of the present state of knowledge on the subject of the use of cathode rays for measurement purposes in electrical engineering, and specially with a view to possible future developments.

Part 1 introduces the subject of measurement methods. Section (I) describes various ways in which information on physical quantities may be obtained by applying them to suitably devised instruments, and in Section (II) is given the history of the development of such instruments, with special reference to those for studying variable quantities. In Section (III) are described various means of producing cathode rays and how they came to be applied to measuring instruments.

Part 2 deals in greater detail with measuring apparatus using cathode rays (i.e. an "electron jet") as a "pointer." Sections (IV) and (V) describe historically the development of such apparatus by successive workers in the field, with brief references to the purposes for which it was devised. Certain special problems arise in the use of such apparatus for accurate measurement, and Sections (VI) and (VII) indicate how the solution of these problems has been tackled. In Section (VIII) the auxiliary apparatus found necessary for the study of variable quantities is described.

Part 3 contains a brief résumé of some of the limitations of the methods described in the paper, and indicates some possible lines of future development.

In an Appendix is given an investigation (partly mathematical and partly historical) of certain essential properties of the electron jet as used in the instruments described.

TABLE OF CONTENTS.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate

PART 1.

INTRODUCTORY.

For a period of more than half a century it has been known that cathode rays are deflected by a magnetic field and also by an electrostatic field; but it was the classic work of J. J. Thomson on the electron, published in 1897, which showed how reasonable precision could be obtained in such measurements.

This notable work in the realm of pure physics paved the way for the application of cathode rays to electrical engineering measurements, and since Braun made the first practical use of these rays, and H. J. Ryan added notably to the subject, there have been an ever-increasing number of investigators working at the development of the cathode-ray tube and its applications. Further, the extraordinarily rapid development of wireless or high-frequency engineering has recently given an even greater impetus to this study.

During periods of rapid progress such as this it is well at times to stand back and make the attempt to survey the entire field, so that one may see more clearly the directions in which new ground may profitably be broken, and also determine as far as possible the limitations.

It is with this object that the preparation of this paper has been undertaken, in the hope that it may prove of real service to many interested in this subject.

Part of the material and some of the work recorded were collected in connection with a research carried out by the authors at East London College for the British Electrical and Allied Industries Research Association during 1922–23, and they desire to record their thanks for permission to make use of it.

(I) METHODS OF MEASUREMENT.

(A) GENERAL.

In the measurement of electrical quantities by direct-reading instruments, an essential function of the measuring instrument is to "convert" the electrical quantity into a form perceptible to the physical senses—usually into a mechanical motion, either of parts of the instrument itself, or controlled by it.

Such motion may take place in one, two or three dimensions. The last-named has scarcely been used: one-dimensional or linear motion is the commonest type employed: two-dimensional motion has already been used to a considerable extent, and it is hoped to show in this paper how its application is extended by modern developments in instruments.

It may be either the displacement or the velocity of the moving pointer or indicator of the instrument

which furnishes the required measure of the electrical quantity. Both are utilized, but the former is the more common.

(B) Classification of Methods.

(1) linear deflectional systems.

The usual commercial electrical instruments are of the steady-deflection type. These instruments serve to measure R.M.S. values of periodic quantities (in a.c. work), as well as steady values (as in d.c. work). By adaptation also, as in the ballistic galvanometer and electrometer, they will furnish information about transient phenomena. But for detailed study of transient quantities and also of periodic variables it is necessary to measure their instantaneous values.

In Section (II) is described the development of instruments that will measure these instantaneous values. Such instruments ("oscillographs," etc.), if used with linear deflection like the steady-deflection instruments referred to above, furnish a ready means of measuring maximum and minimum values of variable quantities,* but in general it is necessary to use them with a two-dimensional method of recording.

(2) two-dimensional systems.

Broadly speaking, the methods of indicating and recording variable electrical quantities which utilize the two-dimensional principle may be divided into two classes; these may best be denoted by the terms "oscillographic" and "cyclographic."

(*a*) *Oscillographic method.*†

The distinguishing feature of the first of these two methods is that the second component motion has as its sole function the provision of a time scale or time co-ordinate, the purpose of this on the indication or record being to render possible a study of the time-variations of the electrical quantity under investigation, as it is reproduced by the first component motion. This first component of the motion is almost invariably imposed upon the indicator of the instrument, as is done in the steady-deflection instruments previously referred to. The second component of the final relative motion is commonly imposed not on the indicator but on the chart or recording plate; this component is usually a continuous uniform motion, and may be either linear, in a direction perpendicular to the first component, or circular, with its centre on the line of action of the first component.

Included in this class are the recording instruments which use a mechanical pen-pointer in conjunction with a paper chart kept in motion by a spring motor; and many types of oscillograph which use an optical pointer, for example, in conjunction with a moving photographic plate or film. Note that in these arrangements only one of the two component motions is available for control by the electrical quantity to be studied; but this does not preclude the use of "double" and "triple" instruments, by which means simultaneous records of more than one such quantity may be superimposed on the same chart [see Section I, C, 2, (*a*)].

A second method of introducing the time-scale motion is to superimpose this on the indicator itself, using a fixed recording screen or plate; in instruments with an optical pointer this is frequently done by means of a rotating or oscillating mirror (synchronized for periodic quantities). In instruments using a "ray" or "jet" pointer the control device used for imposing the second component motion on the pointer may be of the same nature as that used for the first component —in this case, however, we really have a "cyclographic instrument" used for "oscillographic work," but this is a popular combination

(*b*) *Cyclographic method.**

The second, the "cyclographic," method of measurement utilizing the two-dimensional principle, though of more recent development than the first method, is perhaps the most potent method available for investigation of variable quantities as required in modern electrical engineering practice.

The distinguishing feature of this system is that both of the component motions (constituting the resultant relative motion of indicator and screen or chart) are under the control of variable quantities applied to the instrument. The method may be applied in a manner similar to the more usual oscillographic arrangement, viz. one component motion applied to the indicator itself, and the second component applied to the chart (in a direction perpendicular to the first). This arrangement is exemplified in mechanical engineering practice by the engine indicator and by the autographic recording apparatus applied to testing machines.

The most usual arrangement adopted in the electrical cyclograph, however, is a fixed chart or screen, the indicator having imposed upon it both of the component motions. The two control devices used for applying the two component motions to the indicator are usually of similar nature, depending, of course, on the kind of indicator employed. Thus in an electrified-jet instrument the control devices may be either magnetic fields or electric fields, or one of each. With an optical pointer, i.e. a beam of light, as indicator, the control devices are usually both oscillating mirrors, arranged to produce deflections of the light pointer mutually perpendicular. (Examples of the latter method are the arrangements of Puluj † with resonant working, and D. K. Morris and J. K. Catterson-Smith ‡ with non-resonant working.)

(C) Two-dimensional Methods Applied to Periodic Quantities.

(1) general.

One of the chief uses of the oscillogram drawn to rectangular co-ordinates is to present a picture of the variation of a quantity with time. The importance of this requirement is emphasized by the fact that frequently circular and polar oscillograms, and cyclo-

* See Bibliography, (1).

† In the oscillograph only one of the two component motions (of the indicator relative to the recording screen) is under control of an unknown variable quantity. The second component motion has as its sole function the introduction of the time co-ordinate on the record. This motion may be applied either to the recording screen or to the indicator itself.

* In the cyclograph each of the two component motions is under the control of a variable quantity applied to the instrument. Quite commonly one of these quantities is controlled so that it is a known function of time; thus the cyclogram yields the same information as an oscillogram.

† See Bibliography, (2). ‡ *Ibid.*, (3 and 4).

TABLE 1.

Methods of Measurement.

In this table various known methods of measurements are classified according to the definitions of the preceding Section I, B.

	Instruments with linear deflection, i.e. "One-dimensional"	"Two-dimensional" instruments: Oscillographic, Polar co-ordinates	"Two-dimensional" instruments: Oscillographic, Rectangular co-ordinates	"Two-dimensional" instruments: Cyclographic (rectangular co-ordinates)
Steady-deflection instruments	Ammeters, galvanometers, etc. Cathode-ray tube	(Recording pressure gauge)	Recording ammeters, etc. Recording flow-meters	(Not used)
Vibratory instruments: Resonant	Vibration galvanometer Einthoven galvanometer	(May be used for	frequency measurement)	Phase indicators [Puluj (1893) and Leyshon (1923)] Cathode-ray tube [see Braun (1906)]
Vibratory instruments: Non-resonant ..	Oscillographs, including Braun tube [MacGregor-Morris, 1902]	Mechanical oscillograph [Chubb, 1914] Non-mechanical oscillograph [Grix, 1921]	Mechanical oscillograph [Duddell, Blondel, etc.] Non-mechanical oscillograph [Dufour (1914), Watson Watt (1923), Keys (1921)]	Engine indicator, and autographic recorder Duddell instruments [D. K. Morris, 1904] Cathode-ray cyclograph [Ryan (1903), Minton (1915)]

grams when the second quantity has a known time relation, are converted by re-plotting into rectangular oscillograms.

Most forms of cyclograms and superimposed oscillograms, however, involving more than one unknown quantity (in addition to the time scale if one is used) permit the determination of "derived quantities" (such as mean and R.M.S. values of P.D. and current; energy, power, and power factor; frequency relations) by taking suitable measurements from the diagram and making the appropriate calculation on the lines indicated in the following sections.

(2) OSCILLOGRAPHIC METHOD.

(*a*) *With rectangular co-ordinates.*

Suppose that the plane of Fig. 1 represents the recording screen of an oscillograph, and that z is its

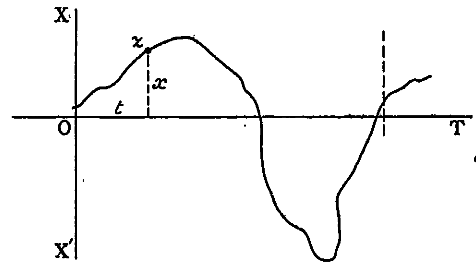

FIG. 1.—Rectangular oscillogram with linear law.

pointer or indicator. Assume also that the axis X′OX is drawn parallel to the motion of z due to the applied electrical quantity, and that the axis OT is the time axis, being the path traced by z when no electrical quantity is applied to the instrument.

Then as the oscillograph is operated by the applied periodic quantity the indicator z moves over the screen and traces out on it a periodic curve; and when the time-scale motion is made to repeat itself and is synchronized with the fundamental frequency of the unknown quantity, the curve repeats, i.e. the indicator travels over the same path again and again.

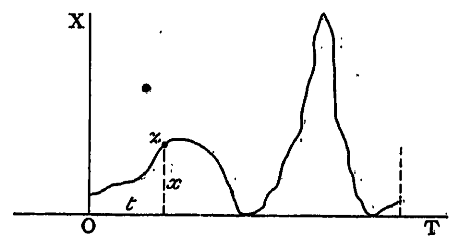

FIG. 2.—Rectangular oscillogram with square law.

Some oscillographic instruments, e.g. the electrometer of Taylor-Jones,* operate on a square law, that is, the deflection x of the pointer z is proportional to the square of the periodic quantity at every instant. Under these circumstances the deflection is never negative (see Fig. 2).

It is easy to obtain the R.M.S. value of the unknown quantity from a square-law oscillogram, for the area under the curve for a complete cycle is easily determined by planimeter, and this area, divided by the length of

* See Bibliography, (5).

the time axis corresponding to one cycle, gives a measure of the "mean square" of the quantity. Introduce the scale factor and extract the square root, and the required value is obtained.

It is not practicable, however, to use these oscillograms for mean values, or values of energy and power (with simultaneous records), primarily because of the ambiguity of sign in calculating from the square root of the measured deflection. For similar reasons ambiguous results follow in the determination of frequency relations. Thus with a "true a.c." unknown quantity (i.e. one whose mean value is zero) the lowest frequency shown by the oscillogram is double the true fundamental frequency.

However, in the majority of modern oscillographs the deflection of the indicator is proportional to the first power of the applied quantity (i.e. a linear law). In this case the area under the curve, divided by the time-period of the quantity as measured on the time scale, gives the mean value (arithmetic mean) of the quantity. But the effective value is usually the more important to determine, and for this the method

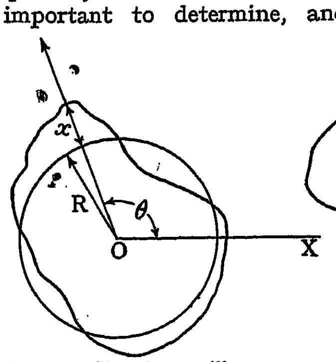

FIG. 3.—Circular oscillogram (with base circle).

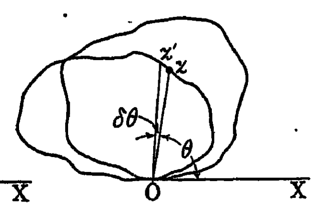

FIG. 4.—Polar oscillogram.

becomes complicated. It is necessary to replot the curve, squaring the instantaneous values (in other words, to construct a "square law" oscillogram), determine the mean of this and extract the square root as above described. Similarly in using superimposed oscillograms, to determine the mean power involves drawing a graph with ordinates at each point equal to the product of the corresponding ordinates of the two simultaneous records. The mean value of this curve is obtained as before, and both scale factors must be introduced. Having thus determined the effective values of a P.D. and a current in the same circuit and the net power flowing, the power factor (and phase-angle, of sinusoidal quantities) immediately follow.

Should the two periodic quantities be nearly alike in wave-form (as for example when both approximate sufficiently to the sinusoidal form), their phase difference may be determined directly from the record, since the scale factor of the time axis is known. From this result the power factor is easily calculated. Under these same conditions accurate determinations of frequency ratios may be made [see Section I, C, 3, (*f*)].

(*b*) *The circular oscillogram.*

When it is desired to make the instrument indicator re-trace the oscillogram regularly, the time-scale motion must be made to repeat. This can be done with the rectilinear motion, by methods to be described in Part 2 (Section VIII). But a simpler way is to use a circular motion instead—this gives rise to the circular oscillogram. Obviously an integral relation must hold between the rotational speed of the circular motion and the frequency of the periodic quantity.

Alternatively the circular oscillogram may be regarded as one constructed upon a "base circle" as time axis instead of a straight line. Thus if the plane of Fig. 3 represents the screen of the oscillograph and z its indicator, the base circle is the path traced by z when no deflecting quantity is applied. When the oscillograph is operated by an applied quantity, the path traced departs from a circle in some such manner as depicted.

Chubb * and Beliavsky † have shown how to determine the effective value of a periodic quantity from a circular oscillogram, and the power and power factor in

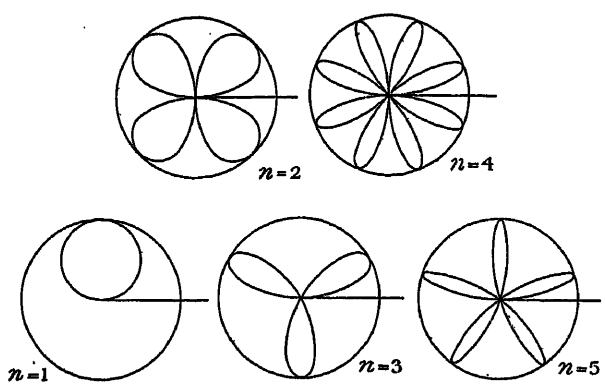

FIG. 5.—Polar oscillogram of a sinusoidal quantity, showing effect of odd and even ratios between frequency of applied quantity and that of time scale.

a circuit from the superimposed oscillograms of the P.D. and the current.

(*c*) *The polar oscillogram.*

The polar oscillogram presents the wave-form of a periodic quantity drawn to polar co-ordinates instead of to Cartesian co-ordinates; it may be regarded as a special case of the "circular oscillogram," in which the base circle has shrunk to zero. As before, let the plane of Fig. 4 represent the oscillograph screen and z the indicator. Then with the time-scale motion in operation, but with no applied quantity, the indicator remains at rest at the origin O. When the periodic quantity is applied, a curve is traced as shown, the radius vector of which is at each instant proportional to the applied quantity. The position of the indicator z may therefore be expressed in the polar co-ordinates r, θ.

The curve closes upon itself and repeats when there is an integral relation between the speed of rotation of the time-scale motion and the frequency f of the applied quantity (see Fig. 5). Thus if n cycles of the periodic quantity occur during each revolution of z, i.e. if when $\theta = 2\pi$, the time $t = nT$ (where T = periodic time = $1/f$), then

$$\theta = t \times \frac{2\pi}{nT}, \quad \text{or} \quad t \times \frac{2\pi f}{n}.$$

* See Bibliography, (0). † *Ibid.*, (7).

Under this condition it is possible to measure with planimeter the area swept out by the radius vector for each revolution of the indicator. The meaning of this measurement may be interpreted as follows *:— Suppose the area to be divided into elemental sectors, each having a central angle $\partial\theta$, and a radius r (the value corresponding to angle θ). Each element may be regarded as a triangle, and its area may be written

$$\partial A = \tfrac{1}{2} \times r\partial\theta \times r = \tfrac{1}{2}r^2\partial\theta$$

By summation in the limit when $\partial\theta$ is infinitely small, the whole area is

$$A = \int_0^{2\pi} \tfrac{1}{2}r^2\partial\theta$$

Now r, being proportional to the applied quantity, is a function of time; the area may therefore be expressed as a time integral instead of as a space integral, thus—

$$A = \int_0^T \tfrac{1}{2}r^2\left(\partial t \times \frac{2\pi}{nT}\right) = \frac{\pi}{nT}\int_0^T r^2\partial t$$

From this it will be seen that the area gives a measure of the "mean square" of the periodic quantity. Therefore by introducing the calibration constant of the instrument and extracting the square root, the effective value is obtained.

Using superimposed oscillograms of P.D. and current, the power and power factor in a circuit may be determined by an ingenious method that has been described

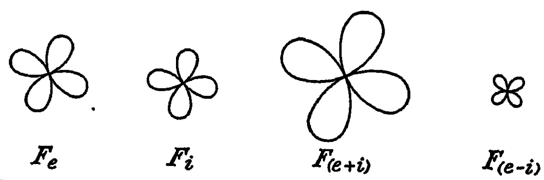

FIG. 6.—Superimposed polar oscillograms (after Grix).

by Chubb,† Grix,‡ and others in the following way:— Oscillograms are taken not only with the P.D. and the current acting separately, but also with them acting together and in opposition. This gives four curves (see Fig. 6) the areas of which may be designated as follows:—

$$A_e,\ A_i,\ A_{e+i},\ A_{e-i}$$

If therefore K_e and K_i are the calibration constants for the P.D. and the current deflections respectively, then

$$A_e = \frac{\pi}{nT}\int_0^T (K_e e)^2\partial t = K_e^2\frac{\pi}{nT}\int_0^T e^2\partial t$$

$$A_i = \frac{\pi}{nT}\int_0^T (K_i i)^2\partial t = K_i^2\frac{\pi}{nT}\int_0^T i^2\partial t$$

$$A_{e+i} = \frac{\pi}{nT}\int_0^T (K_e e + K_i i)^2\partial t$$

$$= K_e^2\frac{\pi}{nT}\int_0^T e^2\partial t + K_i^2\frac{\pi}{nT}\int_0^T i^2\partial t + 2K_eK_i\frac{\pi}{nT}\int_0^T ei\partial t$$

$$A_{e-i} = \frac{\pi}{nT}\int_0^T (K_e e - K_i i)^2\partial t$$

$$= K_e^2\frac{\pi}{nT}\int_0^T e^2\partial t + K_i^2\frac{\pi}{nT}\int_0^T i^2\partial t - 2K_eK_i\frac{\pi}{nT}\int_0^T ei\partial t$$

* Also see Bibliography, (8). † *Ibid.*, (6). ‡ *Ibid.*, (9).

From these results it is possible to separate the term

$$2K_eK_i\frac{\pi}{nT}\int_0^T ei\partial t$$

Now the power consumed in the circuit is the mean value of ei (the instantaneous power) taken over a complete cycle, and therefore

$$\text{Power } (P) = \frac{1}{T}\int_0^T ei\partial t$$

The result then may be stated, that

$$\text{Power } (P) = \frac{n}{2K_eK_i\pi}\{A_{e+i} - (A_e + A_i)\} \quad . \quad (1)$$

or

$$P = \frac{n}{2K_eK_i\pi}\{A_e + A_i - A_{e-i}\} \quad . \quad . \quad (2)$$

or

$$P = \frac{n}{4K_eK_i\pi}\{A_{e+i} - A_{e-i}\} \quad . \quad . \quad . \quad (3)$$

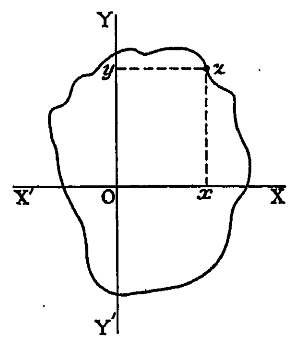

FIG. 7.—General cyclogram.

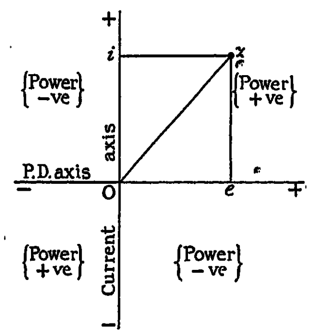

FIG. 8.—Cyclogram of P.D. and current.

The apparent power is the product of the effective values of the P.D. and the current, and is therefore given by

$$\sqrt{\left(\frac{1}{T}\int_0^T e^2\partial t\right)} \times \sqrt{\left(\frac{1}{T}\int_0^T i^2\partial t\right)} = \sqrt{\left(\frac{n}{\pi K_e^2}A_e\right)} \times \sqrt{\left(\frac{n}{\pi K_i^2}A_i\right)}$$

$$= \frac{n\sqrt{(A_eA_i)}}{\pi K_eK_i}$$

and the power factor is the quotient, so, using (3) above, we get

$$\text{Power factor} = \frac{1}{4}\left\{\frac{A_{e+i} - A_{e-i}}{\sqrt{(A_eA_i)}}\right\}$$

(3) CYCLOGRAPHIC METHOD.

(*a*) *General.*

Suppose that the plane of Fig. 7 represents the screen of a cyclograph, of which z is the indicator, and that the axes X'OX, Y'OY are drawn parallel to the two components of the motion of z (each being due to one of the applied quantities), their origin O being the position of rest of the indicator z.

As the cyclograph is operated by the applied periodic quantities, the indicator z moves about over the screen and traces out on it a periodic curve; and when the

quantities have an integral frequency ratio this curve closes upon itself and repeats.

(b) *Properties of the cyclogram.*

(i) *The deflections.*—A common use for the cyclograph is to study the power consumption or other electrical property of an apparatus, or, in general, the relations between a P.D. and a current. Each of these two quantities then will operate one of the component deflections of the indicator, in other words

$$x = K_e \times e$$
and
$$y = K_i \times i$$

where K_e, K_i are the calibration constants of the instrument.

(ii) *Resistance.*—At each instant

$$e/i = r$$

where r is the instantaneous resistance corresponding to the values e and i of the P.D. and current respectively. This derived quantity r is equal to $(x/K_e) \div (y/K_i)$ on the cyclogram (Fig. 8) and it is therefore inversely proportional to the slope of the radius vector from the origin O to the indicator point z.

(iii) *Power.*—Again, since electrical power is measured by the appropriate values of P.D. and current, we have

$$\text{Power } (p) = e \times i$$

This is equal to $(x/K_e) \times (y/K_i)$ and is therefore proportional to the area of the rectangle O*ezi* on the cyclogram. Note, however, that this derived quantity p is the instantaneous value of the power flowing into or out from the apparatus, and holds only for the same instant of time as the instantaneous values e and i.

The sign of this quantity p depends solely on the signs of its two factors e and i. Thus when the indicator z is in the upper right-hand quadrant of the cyclogram (see Fig. 8) the instantaneous power is positive; similarly when z is in the opposite quadrant (bottom left-hand) the power is also positive, i.e. flowing in the same sense; but when z is in either of the two remaining quadrants the power is negative, i.e. flowing in the opposite sense.

In order to obtain the average power it is necessary to evaluate the variations of p for one cycle, integrate with respect to time and divide by the time period, just as with the oscillographic method using rectangular co-ordinates. The quantities power factor and phase angle (in the case of sinusoidal variables) follow in the usual manner.

In power measurement then it is evident that the cyclographic method has so far offered no advantages over the oscillographic method (other than showing changes in sign of the instantaneous power, and therefore the presence or absence of surging energy).

(c) *The area of the cyclogram.*

It has been shown that when the cyclograph is operated by periodic quantities of equal frequency, for example, a closed curve is traced by the indicator. Such a figure encloses a definite area; and it is possible, by correct choice of the quantities used to control the deflections x and y, to make the value of this area represent one of the required results.

In Fig. 9 the diagram traced by the indicator is shown. Suppose it is divided into a number of "elemental strips"; then the area of each strip may be expressed in the form

$$\partial A = y\partial x$$

where y is the length of the strip and ∂x its width. Then the whole area A is the summation of the areas of all the elemental strips, covering a complete cycle of the motion of z. Thus $A = \int y\partial x$ between the limits of one cycle.

If the division of the area into its elemental strips were made parallel to the X-axis instead of parallel to the Y-axis (as in Fig. 10), then by similar reasoning we obtain $A = \int x\partial y$ between the limits of one cycle.

It has been specified for these results that the quantities x and y are periodic functions of time. The

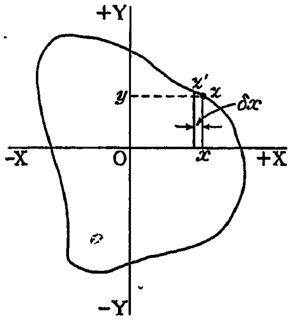

FIG. 9.—Area of a cyclogram.

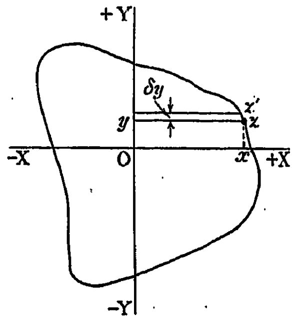

FIG. 10.—Area of a cyclogram. Alternative integration.

area A may therefore be expressed as a time integral instead of as a space integral. Thus

$$A = \int y\partial x$$
$$= \int_0^T y\frac{\partial x}{\partial t}\partial t$$

where T is the time period of one cycle. A similar result is obtained by using the alternative expression

$$A = \int x\partial y$$
$$= \int_0^T x\frac{\partial y}{\partial t}\partial t$$

(d) *Application to power measurement.*

From the foregoing analysis it is apparent that the cyclograph gives automatically an integration with respect to time of the instantaneous product of the two factors y and $\partial x/\partial t$ (or, in the alternative expression, the factors x and $\partial y/\partial t$). This property of the cyclograph may be utilized to give directly (i.e. without any intermediate plotting or calculation) the energy per cycle, and hence the mean power consumed in the apparatus—the necessary condition is that the instantaneous value of the product $y(\partial x/\partial t)$ [or, in the alternative scheme, of the product $x(\partial y/\partial t)$] shall truly represent the instantaneous power in the apparatus.

Suppose now we have chosen one of the components,

say y, to be proportional to the P.D. Then in order to produce the above result we find by simple division that the quantity $\partial x/\partial t$ must be proportional to the current. It follows from this that the second component deflection, x, must be proportional to the time integral of the current, since $x = \int(\partial x/\partial t)\partial t$. Similarly, if we have chosen one of the components to be proportional to the current, it may be shown that the second component must be made proportional to the time integral of the P.D.

It is important to note that, as a result of this choice of the component deflections, the quantity represented by area on the cyclogram is energy; for it is the product of the two deflections, and with either choice of deflections this product is found to be the time integral of power, which is energy. Thus with periodic quantities of equal frequency, the area of the cyclogram figure, which is the net value of the area swept out by the cyclograph indicator during one cycle, represents the net energy passed into the apparatus per cycle. This energy per cycle, divided by the time period (or multiplied by the frequency), gives the mean power consumed in the apparatus. The simplicity of this process—measure an area, introduce the calibration constants, multiply by the frequency—constitutes the great merit of the cyclographic method for power measurement.

(*e*) *The cyclograph as a power-factor meter.*

(i) *Sinusoidal quantities.*—A special case in the determination of power factor from a cyclogram demands attention, viz. when the periodic quantities of equal frequency have a sinusoidal wave-form. In this case, then, we have

$$e = E_m \sin 2\pi ft$$
$$i = I_m \sin (2\pi ft + \phi)$$

where ϕ expresses the phase difference between the two quantities (in terms of the phase angle between their vectors), and E_m and I_m are the maximum values of the P.D. and the current respectively.

(ii) *High power factor.*—If these two quantities directly control the two component deflections of the cyclograph [as suggested in Section I, C, 3, (*b*)], then

$$x = K_e e = K_e E_m \sin 2\pi ft$$
$$y = K_i i = K_i I_m \sin (2\pi ft + \phi)$$

The cyclogram obtained is thus a "Lissajous figure," and in the particular case chosen of equal frequencies it is an ellipse (see Fig. 11).

Note that the maximum abscissæ and maximum ordinates of this ellipse are

$$\pm X = \pm K_e E_m$$
and
$$\pm Y = \pm K_i I_m$$

respectively, i.e. the ellipse is bounded by a rectangle of total length $2X$ and total width $2Y$.

A further property now reveals itself, viz. that when $x = 0$, then $\sin 2\pi ft = 0$, and $2\pi ft = 0$ or π, etc.

Therefore $$y_0 = \pm K_i I_m \sin (2\pi ft + \phi)$$
$$= \pm K_i I_m \sin \phi \quad \text{or} \quad \pm Y \sin \phi$$

Similarly when $y = 0$,
$$x_0 = \pm X \sin \phi$$

Therefore the ratio (intercept of ellipse)/(intercept of rectangle) on either axis is equal to $\sin \phi$. From this, $\cos \phi$, the power factor, is easily determined.

The method is most accurate and most sensitive when the ellipse is narrow, as shown in Fig. 11. In the limit when the ellipse becomes the diagonal of the rectangle,

$$x_0 = 0$$

whence $\sin \phi = 0$ and $\cos \phi$ or power factor $= 1$. This arrangement, then, is the better adapted for use in a.c. power engineering for measuring departure from unity power factor.

(iii) *Low power factor.*—In measuring power losses cases frequently arise where the power factor must be accurately determined when it is in the neighbourhood of zero. For this work it is better to use the mode

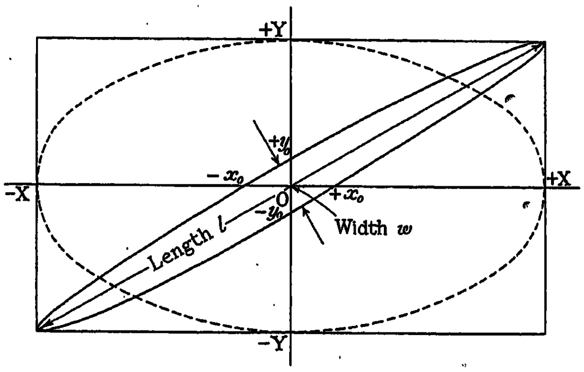

FIG. 11.—Elliptical cyclogram (power-factor determination).

of operation of the cyclograph described in Section I, C, 3, (*d*). Here

$$y = K_i I_m \sin (2\pi ft + \phi)$$
and
$$\frac{\partial x}{\partial t} = K_e E_m \sin 2\pi ft$$
whence
$$x = \int K_e E_m \sin 2\pi ft \partial t$$
$$= -2\pi f K_e E_m \cos 2\pi ft$$

Then when

$$x = 0, \quad \cos 2\pi ft = 0, \quad \text{and} \quad 2\pi ft = \frac{\pi}{2}, \frac{3\pi}{2}, \text{etc.}$$

$$\therefore y_0 = K_i I_m \sin\left(\frac{\pi}{2} + \phi\right)$$
$$= \pm K_i I_m \cos \phi \quad \text{or} \quad \pm Y \cos \phi$$

and by similar reasoning, when $y = 0$,

$$x_0 = \pm X \cos \phi$$

Therefore in this case the ratio (intercept of ellipse)/(intercept of rectangle) on either axis is equal to $\cos \phi$, i.e. the power factor itself.

As before, the method is most sensitive when the ellipse is narrow; in the limit, $x_0 = 0$, giving $\cos \phi = 0$ or power factor zero.

(iv) *Alternative methods.*—When the cyclogram is a narrow ellipse it is sometimes more convenient to measure

its major and minor axes (l and w respectively). Their product gives a measure of the area of the ellipse, and the power factor may be evaluated as the ratio of this area to that of the maximum ellipse that can be contained in the bounding rectangle (i.e. corresponding to unity power factor).

$$\text{Power factor} = \frac{\pi wl}{\pi(2X)(2Y)} = \frac{wl}{4XY}$$

Note that, as in the previous methods, the calibration constants are not required.

An alternative method is to measure the "fineness ratio" of the ellipse, i.e. the ratio of its major and minor axes. When the ellipse is sufficiently narrow [i.e. power factor very small with method (iii) above], the major axis may be taken as equal to the diagonal of the bounding rectangle, or

$$l = 2\sqrt{(X^2 + Y^2)}$$

The geometry of the figure also gives the minor axis as

$$w = \frac{2XY}{\sqrt{(X^2 + Y^2)}} \cos \phi$$

Then the fineness ratio becomes

$$\frac{w}{l} = \frac{XY}{X^2 + Y^2} \cos \phi = \frac{r}{1 + r^2} \cos \phi$$

where $r = Y/X$.

If the two maximum deflections of the indicator can be made equal, i.e. $r = 1$, the expression simplifies as follows:—

$$\frac{w}{l} = \frac{1}{2} \cos \phi$$

whence power factor $= \cos \phi = 2\frac{w}{l}$.

(v) *Partial recording.*—With the above methods of determining power factor from the cyclogram, "partial recording" [see Section VIII, A, 3, (*a*), (i)] may be practised—for if the two tips and the middle slice of the ellipse, and one axis, are recorded, the power factor is determinable. In fact, with the second method under (iv) above, if the cyclograph is adjustable in sensitivity so that constant maximum deflection of the indicator is used, then $r = 1$, and l is constant, so a measurement of one linear dimension (w) is sufficient to determine the result.

(*f*) *Frequency ratios.*

(i) *Absolute measurement of frequency.*—From Section I, C, 2 it is evident that, provided the absolute velocity (as well as the form of variation) of the time-scale motion is known, any oscillogram will furnish sufficient data for determining the time period of the unknown quantity and hence its frequency.

(ii) *Stroboscopic method.*—Stress has been laid upon the necessity for an integral ratio between the frequencies of the two component motions, both with oscillographs (see also Section VIII) and with cyclographs, in order that the indicator when it repeats its cycle shall follow exactly the original path, so producing a stationary diagram. Very slight departure from this condition causes a progressive change in the

TABLE 2.*

Power Measurement Methods.

Provided that suitably-designed instruments are used, the methods in this table are applicable to high frequencies (up to and including radio frequencies).

Method	Measured quantities				Calculated quantity		Remarks
	First	Second	Third				
	E.M.F. or P.D.	Current	Name	—	Name	—	
1. Steady-deflection instruments alone	Electrostatic voltmeter reading True R.M.S. value, independent of wave-form	Hot-wire ammeter reading True R.M.S. value, independent of wave-form	Power	Electrostatic wattmeter reading True value, independent of wave-form	Power factor	True value, independent of wave-form	No information of wave-form given Fails to indicate quick changes in conditions of test
2. Electron-jet cyclograph alone (calibrated)	Maximum component deflection Maximum value only, dependent on wave-form	Maximum component deflection Maximum value only, dependent on wave-form	Power	Area of cyclogram True value, independent of wave-form	Power factor	Dependent on wave-form	Indicates wave-form, and shows instantaneous behaviour of the test apparatus
3. Electron-jet cyclograph as wattmeter only (calibrated)	Electrostatic voltmeter reading True R.M.S. value, independent of wave-form	Hot-wire ammeter reading True R.M.S. value, independent of wave-form	Power	Area of cyclogram True value, independent of wave-form	Power factor	True value, independent of wave-form	Indicates wave-form, and shows instantaneous behaviour of the test apparatus
4. Electron-jet cyclograph as power-factor meter only (not calibrated)	Electrostatic voltmeter reading True R.M.S. value, independent of wave-form	Hot-wire ammeter reading True R.M.S. value, independent of wave-form	Power factor	"Shape" (ratio of linear dimensions) of cyclogram Dependent on wave-form	Power	Dependent on wave-form	Indicates wave-form, and shows instantaneous behaviour of the test apparatus

* Extracted from a Report to the British Electrical and Allied Industries Research Association.

phase relation of the two motions, and as a result the form of the diagram changes, "precessing" through a complete cycle of changes for each cycle (of the lower frequency) by which the phase relation alters. Hence by determining the rate (frequency) of precession in the diagram, we obtain the change of frequency necessary to restore the integral ratio; when this ratio is unity the rate of precession measures the absolute difference between the two frequencies. The method has no frequency limitation (beyond that of the instruments used); and the higher the frequencies under investigation the more sensitive does the method become.

When the quantities studied are sinusoidal, the cyclograph gives the well-known "Lissajous" figures; from the form of the figure it is possible to determine the value of the frequency ratio in use.

(II) DEVELOPMENT OF INSTRUMENTS FOR DELINEATING RAPIDLY VARYING QUANTITIES.

(A) STEADY-DEFLECTION INSTRUMENTS.

To perform its function of "converting" an electrical quantity to be measured into a physical form that is directly perceptible to the physical senses, an electrical measuring instrument must utilize one of the physical phenomena that accompany electricity, for example, the electrostatic, the electromagnetic, the thermal, or the optical effects due to magnetic or electric fields, combined perhaps with pyro-electric, piezo-electric, or other thermal or optical phenomena. It is the appropriate choice of its principle of operation that determines the ability of a steady-deflection instrument to indicate any required function of a varying quantity. On this choice also, and on the mechanical design of the instrument, depends its "law," i.e. the relation between the reading or indication and the quantity measured (whether it be linear, square, or otherwise).

(B) MECHANICAL DELINEATING INSTRUMENTS.

(1) THE NEED FOR VIBRATORY INSTRUMENTS.

In the measurement of periodic quantities it was soon found that more information was required than was given, for example, by the "virtual values." A knowledge of "wave-form" became necessary in order that the growing problems of alternating-current engineering could be solved. By means of the "point by point" method, used first by Lenz (1849) and developed by Joubert * (1880), Rosa † (1898), Hospitalier ‡ (1903), and Lübcke § (1917, with an electron-jet instrument), it was made possible to study the wave-forms of periodic quantities while using only steady-deflection instruments. The method, however, requires much auxiliary apparatus and (with the exception of Lübcke's application) this includes a synchronous commutator, which limits its use to the lower frequencies; it is necessary also for the quantity studied to repeat itself with close accuracy for the considerable time occupied by the test.

* See Bibliography, (10 and 11). † *Ibid.*, (12).
‡ *Ibid.*, (13). § *Ibid.*, (14).

From these considerations it will be seen how great advantage may be derived from the use of an instrument whose indicator will follow the variations of a periodic quantity, and hence give an indication or record of the wave-form.

For the study of transient phenomena the use of an instrument of this description is usually the only solution.

(2) THE RESONANT TYPE.

Wien * (1891) suggested the use of the resonance principle to increase the sensitivity of detectors used in a.c. bridge measurements. The idea was realized in his "optical telephone," and was developed into the vibration galvanometer by Wien (1891), Rubens (1895), Campbell (1907), Duddell (1907), and Drysdale (1912). The string galvanometer of Einthoven † has also been used as a resonance instrument for both low frequencies and radio frequencies (in 1923). ‡

The cyclographic method (two-dimensional) also has been adapted to phase measurements with Lissajous figures by Puluj § (1893), who used two resonant "phase-indicators" acting on the same optical pointer, and by Miss Leyshon ‖ (1923), who used a single instrument.

(3) THE NON-RESONANT TYPE.

Frölich ¶ (1887) first attempted to produce an instrument for wave-form delineation, based on the telephone receiver; the device was improved upon by E. Thomson** (1888), Guyau †† (1913), and Dubois ‡‡ (1923), but like Wien's apparatus it manifests the resonance effect, which, combined with insufficient damping, distorts the wave-form.

An instrument on the lines of the d'Arsonval galvanometer (moving-coil type) was devised by Moler §§ (1892) which he called a "dynamo indicator" by analogy with the steam-engine indicator. The records were traced on a revolving smoked drum; the natural frequency of the instrument was 103 cycles per sec.

Blondel ‖‖ (1891) was the first definitely to state the conditions under which a galvanometer would follow the variations of a periodic quantity sufficiently accurately:—

- (i) High "natural frequency" of oscillation, as great as 50 times that of the phenomenon to be investigated.
- (ii) Damping in the neighbourhood of the "critical value."
- (iii) Self-induction as small as possible.
- (iv) Negligible hysteresis and eddy-current effects.
- (v) Adequate sensitivity.

Blondel's first instrument ¶¶ to fulfil these requirements, called by him an "oscillograph," was of the "moving-iron" type; in its latest form it has a natural frequency of about 40 000 cycles per sec.

Blondel also suggested (1891) the use of the "moving-

* See Bibliography, (15). † *Ibid.*, (16). ‡ *Ibid.*, (17).
§ *Ibid.*, (2). ‖ *Ibid.*, (18). ¶ *Ibid.*, (19).
** *Ibid.*, (20). †† *Ibid.*, (21). ‡‡ *Ibid.*, (22).
§§ *Ibid.*, (23 and 24). ‖‖ *Ibid.*, (25). ¶¶ *Ibid.*, (26).

coil" principle, and this was applied by Duddell * in his "bifilar" instrument; this attains a natural frequency of 12 000 cycles per sec. but has much smaller self-inductance.

These two types of instrument have been of great use for commercial oscillographic work at low frequencies. Both types carry a mirror on their moving parts, for controlling the motion of an optical pointer.

In the Ganz oscillograph the mirror is eliminated, by using a single vibrating strip with microscopic projection for indicating and recording, as in the Einthoven "string" galvanometer. The instrument has a natural frequency of up to 5 000 cycles per sec. and has the advantage of robustness and portability.

Janet † (1894) proposed a chemical method of recording wave-forms on a drum rotating at synchronous speed, and Burch ‡ (1896) suggested the use of the capillary electrometer for a similar purpose. Such methods are necessarily limited to power frequencies, and neither saw commercial development.

A hot-wire oscillograph has been devised by Irwin § (1908); but though it is applicable to power circuits with the help of a special phase-advancer to compensate for the thermal lag, the hot wire alone will not respond accurately to frequencies higher than 5 cycles per sec.

Following upon Taylor-Jones's "short-period electrometer," ‖ produced in 1907 for studying slow oscillations (up to a few hundred cycles per sec.), Ho and Koto ¶ (1913) produced their electrostatic oscillograph. This instrument has a bipolar moving system with mirror like the Duddell instrument, and so has similar damping characteristics and natural frequency (3 300 cycles per sec.); but it is operated by pure electrostatic attraction and is more suitable for high-tension work.

(4) The Limitations of Mechanical Oscillographs.

The types of instrument so far described still use some form of mechanical moving part as the deflectional element, even though the mechanical pointer which serves so well in steady-deflection apparatus has been replaced by an optical device. From this point of view there is no difference of principle between the modern mechanical oscillograph and the early telephone adaptations. Apart from the question of damping, the difference is just one of frequency range.

Blondel,** in developing the theory of the oscillograph whose natural frequency is *above* the range of the frequencies under investigation, showed that there is a definite error in the indication which grows as the frequencies approach one another. For a sinusoidal periodic quantity whose frequency is f, the indicated value falls short of the true instantaneous value in the ratio

$$\frac{\text{Indicated value}}{\text{True value}} = R = \frac{1}{1 + (f/f_0)^2}$$

where f_0 is the natural frequency of the oscillograph.

Then if the error is expressed as a fraction of the indicated value (which is permissible when the error is small) this gives

$$\text{Error } \delta = (1/R) - 1 = (f/f_0)^2$$

Hence, having decided upon the degree of accuracy necessary, the frequency limit of any oscillograph of this type may be determined.

In addition to this magnitude error, the frequency effect includes a phase displacement; but in practice this introduces no error of importance.

In investigating non-sinusoidal and transient quantities, the formulæ given are applicable individually to each sinusoidal component or harmonic present.

No instrument has been developed for measurement purposes having its natural frequency *below* the range of frequencies under investigation; the arrangement is impracticable because of the extremely small sensitivity obtainable. (It may be noted in passing that the idea has been applied to microphones for radio-telephony—here the insensitivity may be countered by amplification.)

(C) Non-mechanical Instruments.

(1) Optical Method.

It is a natural outcome of the use of the optical pointer to consider whether the control of its motion can be obtained without the use of a mechanical moving element, for if so it may be possible to eliminate the frequency limitation of the mechanical oscillograph. In a measure this was accomplished by Pionchon * and Crehore † (1895). The principle utilized is that of the rotation of the plane of polarization of a beam of polarized light traversing carbon bisulphide solution, when immersed in a longitudinal magnetic field. The amount of rotation is indicated by the position of a dark patch on a spectrum, its displacement from its initial position being proportional to the current producing the magnetic field.

The frequency limitation of such an apparatus is imposed only by the response of the carbon bisulphide molecules to the magnetic field, and should cover most electrical engineering requirements. Unfortunately, the solenoid producing the field will have a high inductance; and in addition the sensitivity of the apparatus and the definition of the dark patch "indicator" are very poor, and the apparatus has not been further developed for oscillographic work.

(2) Use of the "Jet" Principle.

A new method, suggested by E. F. Northrup, was experimented upon by Nichols ‡ (1893). The arrangement used was a column of mercury falling vertically from a nozzle supplied by a reservoir. Electrostatic deflection of the mercury jet was tried by two electrodes connected to a Holtz machine, but the apparatus was rather insensitive. Then the jet was placed in a constant horizontal magnetic field, the alternating current to be measured was passed along the jet, and visible deflection resulted. An oscillograph record was obtained on a falling plate, a camera lens giving an image of the position of the jet as it appeared behind a horizontal slit.

* See Bibliography, (27). † *Ibid.*, (28). ‡ *Ibid.*, (29).
§ *Ibid.*, (30). ‖ *Ibid.*, (5). ¶ *Ibid.*, (31 and 32).
** *Ibid.*, (26).

* See Bibliography, (33). † *Ibid.*, (34). ‡ *Ibid.*, (35).

The method was not further developed, but Nichols states that it was introduced "to show that increased accuracy of record may be looked for as the result of reducing in any practicable manner the mass of the indicating device" (page 68 of the paper referred to). We shall see, however, that in this apparatus the reduction of mass, which is not great, is not the cause of its faithful reproduction—it is inherent in the use of the jet principle.

In this apparatus the operating principle is seen to be the mechanical force experienced by a current-carrying conductor placed in a magnetic field, just as in the moving-coil instrument, the Duddell oscillograph or, to take a closer analogy, the Einthoven galvanometer. In these instruments the conductor is rigid and does not move out of the field, so that motion of the conductor takes place more or less as a whole, although the force acting on it is distributed. If the conductor were supported without constraint, then, due to its finite mass, it would move so that its acceleration at any instant was proportional to the resultant force. As a general rule, however, this force is a measure of the electrical quantity under investigation; and by constraining the conductor with an elastic restoring force (usually a mechanical spring) the motion is made such that the displacement of the conductor gives the required measure of the applied quantity.

These conditions, of a finite mass constrained by an elastic force ("elastance"), give inherently a mechanical oscillatory system; and it is from this fact that the problems of natural frequency and resonance arise.

It is important to note that with the jet device the action is quite different from that of a rigid conductor, for although the principle upon which the deflecting force depends is identical (in Nichols's arrangement, for example) there is no elastic constraining force. In spite of this absence, however, we see from the formula

$$Y = \frac{\sigma}{\rho} \cdot \frac{LD}{v^2} *$$

that at any point within the region of action of the deflecting force, the deflection (Y, lateral displacement) is proportional to the deflecting force (σ, force per unit length), the others factors being constants of the apparatus. In other words, the electrical quantity is "converted" into a mechanical deflection without the use of a mechanical oscillatory system.

There is nevertheless a frequency limitation with the jet instrument;* it is shown in the Appendix that the frequency error is equal to a fraction $\left(1 - \frac{v}{\pi f x} \sin \frac{\pi f x}{v}\right)$ of the true value, where v is the jet velocity, x the distance it travels under the deflecting force before observation, and f the frequency of the variable studied. (With the electron jet this limit may be made well outside electrical engineering requirements.)

It may be emphasized here that the mass of the jet (ρ, linear mass density) has no influence on the frequency characteristic of the instrument, because with any substance that will form a jet there will be no appreciable rigidity, i.e. the shear force between one element of length and its neighbour will be negligible.

* See Appendix XI, A, 1, (a), (ii).

(III) PRODUCTION OF CATHODE RAYS IN THE VACUUM DISCHARGE.

(A) ELECTRIC DISCHARGE IN GASES UNDER REDUCED PRESSURE.

(1) PHENOMENA OF THE GASEOUS DISCHARGE.

(*a*) *First reduction of pressure.*

Although air and other gases are usually regarded as perfect insulators, it was shown by Coulomb * (1785) that air conducts electricity very slightly at normal (atmospheric) pressure and temperature, even with low values of electric stress; this conduction is often referred to as the "dark discharge." Under increasing electric stress, the conduction phenomenon changes character, becoming successively the "glow," the "brush" (or "corona"), the "spark," and the "arc" discharge. Although the last four are accompanied by phenomena (e.g. the production of light and sound) capable of detection independently of the electrical effect, practically no use has been made of the fact for the direct measurement of varying electrical quantities. The spark discharge has, however, been used frequently for recording time intervals.

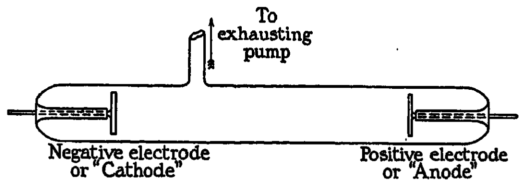

FIG. 12.—Discharge tube for exhibiting electric discharge phenomena in rarefied air.

There are other ways than increase of electrical stress by which a gas may be made to carry an electric current; chief of these is reduction of pressure of the gas. The phenomena accompanying the conduction of electricity through gases under reduced pressure are known to physicists and to those electrical engineers who deal with vacuum discharge apparatus; it is convenient, however, to describe them here in order that we may note in what ways they may be applied to the purposes of electrical measurements, and what are the unique advantages they possess for these purposes in the light of modern requirements.

A closed glass tube (see Fig. 12) with a metal disc electrode sealed into each end, and connected to a vacuum pump, is a suitable apparatus for the study of these phenomena. On the first reduction of pressure it is found that a form of spark discharge will pass which has lost the noisy character of that in free air, and which requires for its production a much smaller value of P.D. applied between electrodes. This discharge soon changes into a "bundle of sinuous and irregular streamers"; these in turn broaden out and after a considerable reduction of pressure of the air in the discharge tube (approaching 1/100th of its original value) the bulk of the tube is seen to be filled with a pink diffuse glow. For this "glow discharge" the P.D. required is only a few hundred volts, so that the

* See Bibliography, (36).

alternative spark-gap of the tube is only a fraction of a centimetre (see Table 3).

(*b*) *The Geissler discharge.*

The glow discharge retains its principal characteristic of luminosity in the gas over a considerable range of pressures. As the pressure of the gas is reduced, however, changes occur in the distribution and intensity of the glow in the discharge tube; these effects are commonly referred to as the Geissler discharges, which Townsend * classifies into four main types:—

First type.—At pressures slightly less than that mentioned, i.e. in the neighbourhood of 1/200th of atmospheric pressure, it is found that a relatively much smaller P.D. suffices to cause a discharge. Under these conditions each electrode is seen to be covered, or partially covered, by a layer of glow; the remainder of the discharge tube is dark.

Second type.—As the pressure reaches the neighbourhood of 1/1 000th atmosphere the two glows extend from the electrodes into the tube. That at the cathode or negative electrode grows to a centimetre or so in thickness, and is known as the "negative glow." That at the anode or positive electrode fills the tube, whatever its length, to within a few centimetres of the cathode; this is called the "positive column." The region between these glows is non-luminous, and is called the "Faraday dark space." In air the positive column is pink, and the negative glow a milky blue.

Third type.—As the pressure of the air is reduced to about 1/3 000th atmosphere the positive column tends to break up into button-shaped portions, called "striæ"; these are regularly spaced and have their convex sides facing the cathode. Meanwhile the positive column has shrunk in length, the remaining portions of the discharge expanding. At this stage the walls of the discharge tube are seen to fluoresce with an olive-green

TABLE 4.—*Gaseous Discharge Phenomena.*

Approximate gas pressure, in millionths of an atmosphere	Phenomena in air
	Spark discharge loses its noisy character, and is replaced by sinuous irregular "streamers" which broaden out and fill the tube with a pink diffuse "glow."
	"Geissler" discharges.
	1ST TYPE.
5 000–10 000	Gas is now highly conducting—discharge may be passed with a few hundred volts. Each electrode partially covered by a layer of glow—rest of tube dark.
	2ND TYPE.
2 000–5 000	The two glows extend outwards into the tube—"negative glow," milky blue, about 1 cm thick; "positive column," pink, fills tube to within a few cm of the cathode; two glows are separated by the "Faraday dark space." The gas is passing its point of maximum conductance.
	3RD TYPE.
1 000–2 000	Positive column tends to break up into "striæ," which thicken and then diminish in number, intensity and extent.
500–1 000	Walls of tube fluoresce (olive-green if soda glass, bluish-green if lead glass) due to "discharge rays."
	4TH TYPE.
200–500	Negative glow detaches itself from the cathode like a shell—being separated from it by the "Crookes dark space." A new velvety film ("cathode glow") spreads over the cathode surface.
100–200	Phenomena at cathode expand at expense of the rest. Positive column disappears, but a thin "anode glow" persists. Negative glow finally loses all luminosity.
10–100	Anode glow disappears, and cathode dark space expands, until eventually it fills the tube, the gas as a whole being non-luminous.
1–10	Glass walls show a bright fluorescence due to bombardment by "cathode rays" (with soda glass, apple-green, familiar from X-ray tubes). The conductance of the tube has been diminishing, until, at this point, many kilovolts are required to pass the discharge. Fluorescence diminishes, and finally tube ceases to conduct.

light (if of soda glass; lead glass gives a bluish-green), which J. J. Thomson * has shown to be due to extremely active ultra-violet radiation ("discharge rays") from the negative glow.

Fourth type.—Further rarefaction of the air carrying the discharge causes further development of the phenomena at the negative electrode, and shows that the negative glow has become sharply separated from the cathode by a second non-luminous region, called the "Crookes" or "cathode" dark space; the cathode also is enveloped in a velvety film of light, known as the "cathode glow."

When a pressure of about 1/10 000th of an atmosphere is attained these phenomena are found to occupy most of the tube; the positive column has disappeared as such, there being only the thin anode glow over the surface of the anode. With air at this pressure, in a discharge tube 3 cm in diameter and 22 cm in length between electrodes, the Crookes dark space has expanded to about 1·5 cm thickness, and the negative glow, which is fainter and more indefinite, occupies 10 to 12 cm of the length of the tube. The fluorescence of the glass also disappears with weakening of the negative glow.

(*c*) *The generation of cathode rays.*

Exhaustion of the discharge tube beyond the region of the Geissler discharges, i.e. beyond about 1/10 000th or 100 millionths of an atmosphere, causes rapid changes in the discharge phenomena. The anode glow disappears and the cathode dark space expands, driving the remains of the negative glow before it. It is now possible to detect luminous streamers which appear to have a definite direction normal to the surface of the cathode, and penetrate a little way along the length of the tube. Under certain conditions the streamers tend to concentrate into a bundle along the axis of the tube, and their colour shows as a rich purplish blue, quite different from the milky blue of the negative glow. Sometimes also there are scintillations on the surface of the cathode, as though due to bombardment.

As a pressure of 1/100 000th or 10 millionths of an atmosphere is approached, the cathode dark space expands until it fills the tube, and the negative glow disappears, so that the gas as a whole is non-luminous. At this stage the walls of the tube show a bright green fluorescence wherever the dark space reaches the walls. (In the case of soda glass it is an apple-green, quite different from and brighter than the olive-green fluorescence obtained at higher pressures.)

The study of the green fluorescence on the glass was commenced by Plücker † in 1859, and carried on by Hittorf ‡ (1869), Goldstein § (1876) and Wiedemann in Germany, Crookes || (1879) in England, and Puluj in Austria. It was soon ascertained that the fluorescence was produced by something coming from the region of the cathode, for a suitably interposed obstacle cast a sharp shadow on the walls of the tube. Goldstein thought it was a form of ether radiation, and gave it the name "cathode rays." Crookes (1879–85), who studied the velocity of the cathode rays at various stages of the discharge, suggested that the rays consisted of electrified particles of some very attenuated form of matter (a "fourth state"), projected with high velocities by the electric forces near the surface of the cathode. Perrin * in 1895 showed that the charge was negative; and J. J. Thomson † in 1897–98 demonstrated that the particles had a mass of 1/1 850th of

that of the hydrogen atom, and that their charge was equal to that carried by the hydrogen ion in liquid electrolysis. The particles are now known by the name "electron" suggested by Johnstone Stoney.

(2) THE MECHANISM OF THE DISCHARGE.

The theory of the gaseous discharge * shows that in general the current is carried by both positive and negative carriers. At the low gas pressure in question, the negative carriers are for the most part in the free or electronic condition; it is these electrons which form the cathode rays. The positive carriers, however, are always gaseous ions, i.e. positively charged molecules or atoms of the gas in the tube; these also acquire appreciable velocities and in suitable apparatus may manifest themselves as "positive rays." Owing to their smaller mass, therefore, the mobility of the negative carriers is much greater than that of the positive.

Numerous observers † have investigated the distribution of electric field strength in different parts of the gaseous discharge; and it is found that over the whole range of gas pressures dealt with in the previous sections there is always a high value of electric field in the neighbourhood of the cathode (giving rise to the cathode fall of potential). As a result of this strong field, ions are rapidly removed from the space in front of the cathode (the Crookes dark space); the negative ions, being more mobile, are removed faster than the positive ions, and these latter consequently preponderate and form a powerful positive space-charge. This space-charge, occurring as it does in close proximity to the negatively charged cathode, is sufficient cause for the high values of electric field. The two phenomena are thus interdependent; it is not necessary here, however, to discover which is cause and which is effect.

The negative ions or electrons, moving under the influence of the electric field, accelerate until their energy is sufficient for ionization by collision; the region where this occurs is marked by the negative glow. On an average an electron travels a distance called its "mean free path" before it collides with any gas molecule; therefore the distance between the cathode and the nearest point of the negative glow—in other words, the dimension of the Crookes dark space—is an approximate measure of this mean free path. It is apparent, therefore, why this dark space expands on reduction of the gas pressure.

Similarly the positive ions, supplied from the negative glow, accelerate towards the cathode; but, due to their lesser mobility, it is not until they come right against the cathode surface, where the electric field is greatest, that their kinetic energy is sufficient to produce ionization. In interpreting the results of Ebert ‡ (1900) on the thickness of the Crookes dark space, J. J. Thomson considers that the negative ions are produced mainly in the region of gas lying about ½ mm in front of the cathode (at the higher pressure this region shows the cathode glow). On the other hand, the fact that the cathode fall of potential depends somewhat on the metal employed for the cathode would suggest that electrons may also be emitted by the cathode itself under the action of the rapidly moving positive ions.

* See Bibliography, (49, 50, 51 and 52). † *Ibid.*, (53 54, 55, 56 and 57). ‡ *Ibid.*, (58).

Villard * (1899) clearly demonstrated the action of the positive ions on the cathode. He used a discharge tube fitted with an insulated diaphragm placed parallel to the cathode and fixed between it and the anode. This diaphragm had two holes in it; when the Crookes dark space extended to it (as occurs when the pressure is low enough for cathode-ray production) the only positive ions striking the cathode are the two streams through the two holes; and the points of impact, opposite these holes, are the only parts of the cathode from which cathode rays are emitted. This is conclusive proof that a high value of electric field at the surface of the cathode is not the only condition required for the emission of electrons. Nevertheless, once electrons are available, the electric field at the surface of the cathode, representing as it does the bulk of the potential drop through the discharge tube, is the determining factor in accelerating the electrons, and hence controls the direction and velocity of emission of the cathode rays.

(3) PROPERTIES APPLICABLE TO ELECTRICAL MEASUREMENT.

(a) Properties of the glow discharge.

(i) *The oscilloscope.*—In studying the Geissler discharge in its first stage (see Section III, A, 1—pressure for air about 1/200th atmosphere), H. A. Wilson † (1902) measured the current density at a cylindrical wire cathode when the negative glow does not envelop the whole of the negative electrode. Under these circumstances the glow assumes the shape of a test-tube, with a well-marked lip at the end furthest from the anode; as the current in the discharge increases, the glow reaches further along the electrode, the length of the glow being proportional to the current.

Wehnelt ‡ (1902) has shown that the discharge from the cathode is confined to the area covered by the glow and that the current density is constant over this area. H. A. Wilson demonstrated that these laws hold in air over a pressure range of approximately 1/100th to 1/30 000th atmosphere (the value of the current density being approximately proportional to the pressure).

From this property of the glow discharge we see that it can be used for the direct measurement of electric current; and moreover, being an ionization phenomenon, it shows a quick response to current variations, so that it may be used for oscillographic work. The oscilloscope and the ondoscope illustrate its application.

(ii) *Use of neon.*—We have so far discussed the phenomena of the glow discharge as they occur in rarefied air. The substitution of other gases or gaseous mixtures does not in general alter the character of the discharge. It may affect the values of gas pressure at which the various stages of discharge occur; it will also affect the values of P.D. required across the discharge tube to establish and maintain the discharge.

A notable instance of this is the use of rarefied neon

* See Bibliography, (59). † *Ibid.*, (60). ‡ *Ibid.*, (61).

to carry the discharge; with this gas the minimum P.D. required to maintain a Geissler discharge of the first or second types, for example, averages about one-third to one-half the value necessary with air. This fact is an important factor in the development of the oscilloscope as a practical electrical measuring device.

For 6 mm carbons	74·6

(*b*) *Properties of cathode rays.*

(i) *Energy of the rays.*—The fluorescence shown by glass when bombarded by cathode rays, which led to their discovery (by Plücker, 1859), is shown to a very intense degree by certain crystalline minerals, and is now used universally for visual indication of the rays. Bombardment by the rays may also cause chemical and physical changes in matter, as for example the photographic sensitive plate, which is chemically altered by light. As the rays consist of particles of finite mass moving with high velocity, they possess considerable kinetic energy. Wiedemann || (1898) has shown, however, that only a small fraction of this energy is spent in exciting fluorescent radiation. Portions of the energy are converted into X-rays or into secondary cathode rays; but usually the bulk of it is dissipated as heat at the point of impact. (The X-ray tube shows this evolution of heat at its target, which is subjected to bombardment by a concentrated jet of rays.)

...mission *of the rays.*—Goldstein, by suitably-...ow experiments, confirmed Hittorf's observation that the rays travel in straight lines, and showed further that they start at right angles to the surface of the cathode (the rays give no "penumbra" effect as light does). These two properties of perpendicular emission and rectilinear propagation are easily accounted for by the "cathode fall of potential" phenomenon (see Section III, A, 2), and it will be seen that they are essential to the application of the cathode rays to electrical measurement purposes. The effect may be observed directly in the vacuum discharge tube by adjusting the gas pressure to a suitable value (in the neighbourhood of 100 millionths of an atmosphere) such that the trajectory of the rays becomes visible as a pencil of blue light.

(iii) *Deflection of the rays.*—The cathode rays are deflected by a magnetic field having a component perpendicular to their direction of travel, a property first noticed by Plücker * (1859). The direction of the deflection is the same as that of a flexible conductor lying in their path and carrying an "electric current" towards the cathode.

The rays are also deflected by an electrostatic field, as was indicated by the experiments of Goldstein (1876) and Perrin (1895), and finally demonstrated by J. J. Thomson (1897). The difficulty experienced in realizing the electrostatic deflection is due to the very intense ionization produced by the rays in the residual gas through which they pass (as evidenced by the blue streamers of light by which they are first seen). This ionization renders the gas partially conducting, and the resultant effect is as though the rays were moving down a kind of protecting conducting cylinder of their own construction and are thus screened from the action of any electric field applied to the tube, there being, of course, no electrostatic field inside a closed conductor. The effect may be partially eliminated by more complete exhaustion of the discharge tube (to, say, 10 millionths of an atmosphere), thus reducing the amount of residual gas.

(B) USE OF THE ELECTRON JET ("CATHODE-RAY PENCIL") PRODUCED BY GASEOUS DISCHARGE.

(1) REQUIREMENTS.

The property of the cathode rays which renders them useful for measurement purposes is their sensitiveness to deflection by electric and magnetic fields. But the discharge tube that has served so far to show the rays is not suitable as a measuring instrument. It is necessary, for one thing, to separate the rays from the other phenomena of the discharge, so that their response to the deflecting fields may not be affected by disturbing factors. Secondly, and perhaps more important, means must be adopted for measuring the deflection of the rays with more certainty and accuracy.

(2) CROOKES'S APPARATUS.

The first attempt to fulfil such conditions was made by Crookes † (1879) in studying the relative velocities of the cathode rays as the gas pressure was reduced. The apparatus used consisted of a

...aphy, (60). † *Ibid.*, (62). § *Ibid.*, (64 and 65).

* See Bibliography, (41). † *Ibid.*, (45).

vacuum tube with a plane aluminium electrode; parallel to this and $2\frac{1}{2}$ cm in front of it was placed a mica screen with a small hole in the centre. The rays which were projected through the aperture in this screen were received on a glass plate, the small area on which they impinged being marked by a green fluorescence.

(3) Thomson's Apparatus.

For his determinations of the physical constants of the electron, Thomson * (1897) found it necessary to secure a much greater accuracy of measurement. To obtain this he devised the form of discharge tube shown in Fig. 13. A and B are two thick metal discs, which fill the cross-section of the tube and thus separate it into two main portions. Both these metal discs or diaphragms are earthed by the side connection shown. A negative potential is applied to the electrode C, and a discharge is established in the left-hand end of the tube; thus A acts as anode and C as cathode. The electrode C is flat, with its plane perpendicular to the axis of the tube; as a result the

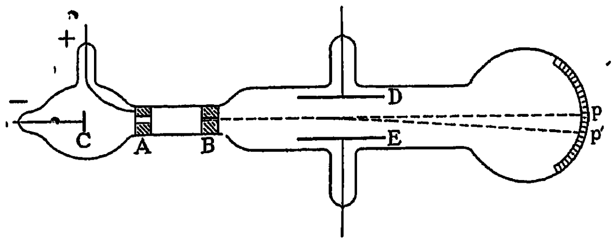

Fig. 13.—Thomson's apparatus for producing an electron jet.

cathode rays generated due to the high exhaustion are projected parallel to the axis, and some of them, instead of being stopped by the anode A, pass through the slit cut in it. These rays that pass through meet B; but the slit in B, though narrower, is parallel to that in A, and therefore a good proportion of the rays will continue in their motion, and form a jet which travels axially along the large right-hand " deflecting chamber " of the tube, eventually bombarding the glass and causing fluorescence thereon at p.

Note first that the discharge is confined to the cathode end of the apparatus, and therefore the rays travelling in the remaining portion of the apparatus are independent of this discharge (except in so far as they are generated by it). Secondly, due to the use of the fine slit in B, the jet of rays which emerges into the deflecting chamber is in the form of a flat strip or thin ribbon; the fluorescence produced on the glass at p therefore takes the form of a short band or line of light, which in its middle portion at least is narrow and sharply defined. It is possible then to make accurate measurements of motions of this line " indicator " in the direction perpendicular to its length.

The electrodes D and E form a condenser for producing an electric field through which the electron jet must pass and which produces a deflection of the jet in the required direction. They are placed inside the apparatus to avoid screening due to conduction on the surfaces

* See Bibliography, (67).

of the glass walls [see Section III, A, 3, (*b*), (iii)]. A deflection may also be produced by means of a magnetic field applied perpendicular to the axis of the tube.

(4) Braun's Apparatus.

The first application of cathode rays to commercial measurements was made by Prof. F. Braun,* also in 1897. This apparatus was much larger than Thomson's and yet simpler in design; it is shown in Fig. 14. K is the cathode, a plane disc perpendicular to the axis of the tube, as before. The anode A, however, is removed to a side tube, so that it is entirely clear of the path of the rays. There is only one diaphragm, C, of metal (aluminium or tin-foil) and it is left insulated; instead of a slit it has a circular hole (about 2 mm diam.). Thus the important result is secured that the jet of rays issuing from the hole and travelling down the tube is cylindrical. Another important modification is the introduction of the " fluorescent screen," a mica plate D coated on the side bombarded by the rays with a fine layer of mineral substance, chosen for its very intense fluorescence under cathode-ray bombardment. This screen then shows a bright round spot of light where the cathode-ray jet falls upon it, and it is possible to measure deflections of it in any direction across the screen; that is, the

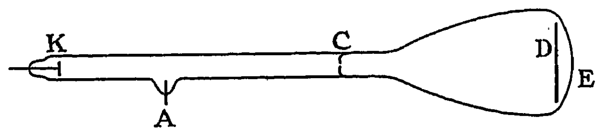

Fig. 14.—Braun's apparatus for producing an electron jet.

instrument gives two-dimensional indications and therefore is a true cyclograph.

(C) Alternative Means of Producing the Electron Jet.

(1) Limitations of the Gaseous Discharge.

Consideration of the theory of the discharge in the cathode-ray tube (see Section III, A, 2) shows that the supply of electrons in a free state, i.e. available for the production of cathode rays, is an integral part of the mechanism of the discharge. Thus with the type of discharge so far discussed there are several severe limitations on the operating conditions. The gas pressure must be reduced to quite a low value (compared with the relatively wide range of values over which the glow discharge phenomena are exhibited). At this pressure the gas has passed far beyond its point of maximum conductance, so that a high P.D. is necessary to produce a satisfactory electron jet in the apparatus; further, the resulting high velocity of the jet renders it comparatively insensitive to deflection, especially by electric fields (see Section XI, B, 3), and so restricts the utility of the instrument in practical engineering. Further, the discharge in the tube carries only a minute current, and in spite of the high velocity this limits the amount of power carried by the jet and hence its ability to produce records with high velocities of traversal.

* See Bibliography, (68 and 69).

It is necessary also that the gas pressure shall remain within certain close limits—a ratio of 1 : 3 is quoted as the average permissible range of variation. This necessitates great care in the construction of cold-cathode instruments (see also Section IV) if they are to maintain satisfactory operation over a reasonable period.

(2) ALTERNATIVE SOURCES OF ELECTRONS.

From these considerations it will be realized that any device which provides a source of free electrons at the cathode of the discharge apparatus will enable some of these limitations to be overcome. There are many of the radioactive substances that emit β rays, which are electrons ejected from the active substance. If, therefore, the cathode surface were covered with a layer of suitable active material, the desired free electrons would be provided, independently of the discharge conditions. The electrons are, however, ejected from the material with velocities usually much higher than those of cathode rays produced by the gas discharge; the problem of harnessing these and directing them down the discharge tube at any desired velocity presents great experimental difficulties. Further, the quantity of electrons obtainable from such a source, bearing in mind the cost in relation to the requirement of a cheap, practical instrument, is certainly too small to permit of selection of the minute fraction that would be passed by a diaphragm such as is used with the cathode rays. Additional complications requiring to be guarded against are the emission of α rays, causing deterioration of the apparatus, and of γ rays, involving danger to the operator of the instrument.

Alternatively, by making the cathode of a suitable metal and subjecting its surface to electromagnetic radiation, electrons may be released from it by virtue of the photo-electric effect. These "photo-electrons" have small velocity and so are available for conversion into cathode rays by an accelerating voltage in the usual manner. Unfortunately, however, the supply of electrons obtainable from a surface of reasonable size is too meagre for practical use.

(3) THERMIONIC EMISSION.

Many experimenters from 1725 onwards have made observations on the electrification produced by hot bodies. Elster and Geitel (1882–89) investigated the effect as produced by incandescent metal wires, and showed that the results were complicated by effects of the gas surrounding the wire, and other causes. Thomson first eliminated these extraneous effects by using a discharge vessel continuously exhausted, and showed that in a high vacuum a metal when first heated emitted a small quantity of positive electricity, but on being raised in temperature it emitted negative electricity at an ever-increasing rate. Edison, Preece (1885) and Fleming (1890, 1896) noted and studied a similar effect with carbon filaments of electric lamps.

J. J. Thomson * (1899) measured the ratio of charge to mass of the negative carriers emitted by an incandescent carbon filament in a high vacuum, and showed that they were of the same nature as the carriers in the cathode rays, i.e. free electrons.

* See Bibliography, (70).

Wehnelt * (1904) found that the emission of negative electricity from certain salts, notably oxides of the alkaline earth metals, was of much greater magnitude than had been noted with other substances.

(4) INTRODUCTION OF THE HOT CATHODE.

(*a*) *Effect on the discharge.*

It has been shown (see Section III, A, 2) that in the gas discharge the region of gas in the neighbourhood of the cathode is rich in positive ions but poor in negative ions, this being the condition that gives rise to the cathode fall of potential.

Schmidt † (1903) showed experimentally that if by any convenient method negative ions are introduced into this region, so preventing this impoverishment, then their presence results in a lowering of the potential drop at the cathode.

Wehnelt ‡ (1904) used calcium oxide or barium oxide mounted on a strip of platinum foil arranged to be heated by an electric current; this device, sealed into a discharge tube and connected as cathode, served as a plentiful source of negative ions when heated, due to the thermionic emission described in the previous section. With this "hot cathode" the potential drop at the cathode may be reduced to a few volts, whereas its value with a "cold cathode," when penetrating cathode rays are being produced, is many kilovolts. Thus with the anode placed close to the cathode (to eliminate the positive column) a current could be sent through the discharge tube with a P.D. of little over 20 volts.

Wehnelt § further showed that by increasing the P.D. applied to his discharge tube, and at the same time limiting the thermionic emission of his cathode (by control of its temperature), the rate of disappearance of negative ions caused by the passage of the current could be made to exceed the rate of emission; by this means a potential-drop could be re-established at the cathode, of any desired value, depending upon the amount of surplus P.D. applied to the tube. By this means, therefore, it was possible to produce cathode rays of any desired velocity (since their velocity is dependent on the electric field that accelerates them, and therefore on the cathode fall of potential).

It is important to note that the function of the hot cathode applied to the discharge as above described is really of the nature of a stimulant to a mechanism already existent; for although the hot cathode certainly introduces electrons by virtue of its own thermionic emission, the discharge is still being carried largely by gaseous ions. The increase in the current carried in the discharge is due not so much to the electrons liberated and accelerated by the applied P.D. as to the extra ionization that these produce. In fact, there is always a strong tendency for a discharge of this type to develop into an arc discharge. In this connection Wehnelt states that it is not advisable to use a P.D. higher than 1 000 volts in his apparatus (see also the next Section) as otherwise the intense positive-ion bombardment causes cathode rays to come off from that part of the

* See Bibliography, (71). † *Ibid.*, (72). ‡ *Ibid.*, (71). § *Ibid.*, (73).

platinum strip that is bare, resulting in bad disintegration.

(b) *Wehnelt's apparatus.*

In 1905 Wehnelt* designed an electron-jet instrument incorporating the hot-cathode device previously described; this is shown in Fig. 15. K is an edge view of the platinum strip, stretched between two supporting wires; A is a metal diaphragm which serves also as anode; S is a screen coated with fluorescent material, as used in Braun's apparatus. C_1 and C_2 are two condenser plates for electrostatic deflection of the jet, as used by J. J. Thomson. The strip K carries on its side facing the anode a spot of lime, about the size of a pin's head; and when a P.D. of a few hundred volts is applied between the hot cathode and the anode an intense stream of cathode rays is emitted from the lime spot, their path being marked by a bright blue line showing ionization of the residual gas.

Since the width of the strip of platinum is greater than the diameter of the electron source, i.e. the lime spot, the intense field at the cathode surface will not depart much from perpendicularity to the surface; this is the more true, the higher the cathode fall of potential that is used. As a result, then, the rays are given the

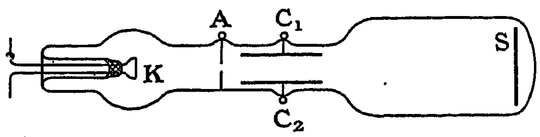

FIG. 15.—Wehnelt's apparatus for producing an electron jet.

bulk of their momentum perpendicular to the cathode surface, and so tend to form a parallel beam of diameter corresponding to that of the lime-spot source.

Thus, limiting the size of the lime-spot source contributes dually to the fineness and intensity of the cathode-ray stream produced by the apparatus, independently of the use of a diaphragm—first by limiting the initial diameter of the stream, and secondly by ensuring that the effective part of the accelerating field shall be more nearly parallel.

With the gas pressure in such a discharge tube reduced to a sufficiently low value, in the neighbourhood of 10 millionths of an atmosphere, as for the cold-cathode discharge, the absorption of the rays by the residual gas is decreased, and a fine pencil of them passes through the aperture in the electrode A, forming the "electron jet."

(5) NEW PROPERTIES OF THE ELECTRON JET.

Wehnelt (1905) first demonstrated the enormous increase in sensitivity that could be obtained from a jet instrument when fitted with his hot lime-spot cathode, and run on a lower P.D., and showed that it was due to the lower velocity of the cathode rays as compared with those of the Braun tube previously used (see also Appendix). This increased sensitivity of the electron-jet instrument greatly enhances its utility for all manner of investigations. An additional advantage is the lower P.D. used on the instrument—it becomes possible to run it from public mains, or even from batteries—so that the complete apparatus may be made portable if desired; for a small accumulator suffices to supply heating current for the cathode strip. The independent source of electrons also enables the current carried by the discharge, and hence the intensity of the electron jet produced, to be increased at will independently of the P.D. used, thus increasing the power available in the jet for registration purposes.

There are disadvantages, however, in the use of a low jet velocity, primarily because of the "absorption" of the rays by the residual gas in the apparatus. Glasson (1911) found that the ionization produced by an electron per unit distance travelled was inversely proportional to the square of its velocity—thus by decreasing the velocity of the jet in the ratio of 10 : 1, as is possible in changing from a cold-cathode to a hot-cathode instrument, the ionization per unit distance is increased in the ratio 1 : 100. However, not all of the collisions of the electrons with molecules are productive of ionization, so that the disparity between the absorptions of slow and fast rays will not be so great. The effect may be observed even in the cold-cathode tube with a higher gas pressure [see Section III, A, 1, (c)]—the cathode rays, so long as their speed remains high, pursue an even course; as they slow down they become more and more liable to deflection by the encountered molecules, until finally they lose so much energy as to be indistinguishable as cathode rays.

There is a further cause contributing to the "loss of entity" of an electron jet, and that is the divergence or scattering of the jet due to the mutual repulsion of the like-charged electrons. It is shown in the Appendix that the rate of increase of diameter of the jet is a function of time, and that a slow jet shows a larger scattering than a fast one, due to its longer time of transit from source to screen.

(D) THE PURE ELECTRONIC DISCHARGE.

(1) ELIMINATION OF THE POSITIVE ION.

The values of thermionic currents from heated substances obtained by different observers had varied between wide limits. Moreover, the substances usually worked with (platinum and carbon) are so difficult to free completely from absorbed gas that it was thought the emission phenomenon might be closely bound up with the presence of gas in the metal—as indeed it is in the case of positive ion bombardment. It seemed, therefore, that with the cleaner conditions, i.e. greater freedom from gas, that could be realized with the use of tungsten, the thermionic currents might cease altogether. In fact H. A. Wilson (1903) stated the probability that a pure platinum wire heated in a perfect vacuum would not discharge any measurable quantity of electricity, either positive or negative. The experiments of Langmuir, however, were reassuring—he found that after a certain high degree of exhaustion had been reached, the thermionic currents increased up to a certain limiting value as the tube became freer and freer from gas.

Coolidge (1913) when working even with tungsten electrodes in a tube designed so that the electrodes could be heated in situ to very high temperatures,

* See Bibliography, (74).

found that the positive ion effect would persist for hours, disappearing completely, however, as the electrodes became sufficiently freed from gas. He pointed out also that although the idea of using a hot cathode was not new (e.g. Wehnelt's experiments, see previous Section) the principle had not previously been applied successfully in such a high vacuum that the positive ions did not play an essential rôle. Thus in his hot-cathode X-ray tube Coolidge * used a filament of tungsten wire as cathode, which with a temperature range of 1 890° to 2 540° K. produced a sufficiently copious supply of electrons (up to 40 mA could be passed through the tube), the amount being dependent only on the temperature of the filament, and independent of the vacuum conditions. In other words, gaseous conduction played no part in the discharge, the current being carried wholly by the electrons liberated at the cathode. To secure this result great care was necessary in the exhaustion of the tube—the heating to incandescence of the electrode in situ, and the baking of the glass envelope while being exhausted; the pressure reached did not exceed a few hundred millionths (1×10^{-8}) of an atmosphere.

(2) ADVANTAGES OF ELECTRONIC DISCHARGE.

One of the main advantages of securing satisfactory operation of an electron-jet instrument with a purely electronic discharge is that since the residual gas is no longer required to play any part in the discharge it may be removed as completely as manufacturing technique will allow. Thus one of the chief obstacles to the successful use of low-velocity jets, viz. the absorption of the "rays" by the residual gas, is removed. Practically, however, there are other factors of even greater importance. The Wehnelt type of cathode is not a satisfactory device for use in a commercial instrument—it shows "fatigue" effects, and it emits gas, so that it is not possible with it to reach the high vacuum necessary for a pure electronic discharge. These disadvantages are doubtless due largely to the positive ion bombardment that necessarily accompanies the gaseous discharge.

PART 2.

DEVELOPMENT OF THE ELECTRON-JET INSTRUMENT.

(IV) THE COLD-CATHODE INSTRUMENT.

The apparatus described by Braun † (1897), which has been described (Section III, B, 3), was used by him first as an oscillograph with one-dimensional deflection of the indicating spot of light viewed through a rotating mirror. Subsequently he used the instrument as a cyclograph for investigating phase relations with polarized electrolytic cells. With this method he obtained stationary curves on the fluorescent screen (as explained in Section I). Electromagnetic deflection of the jet was used. Braun says little about experimental difficulties in the use of this new apparatus, the satisfactory construction of the tubes being left in the hands of the makers, Herr Franz Müller, of Bonn.

Two years later Zenneck * sent to the same manufacturer for cathode-ray instruments, and as a result of his use of them made certain improvements in the design. He used two separate diaphragms in place of one, and used a metal plate with a hole in it, like a diaphragm, as the anode instead of the small electrode

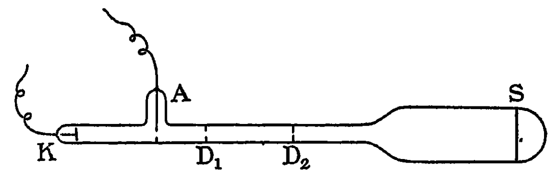

FIG. 16.—Zenneck's tube.

in a side tube. Thus in effect the rays are "stopped-down" three times instead of once (see Figs. 16 and 17).

The tube was used as an oscillograph with a uniform time deflection applied to the electron jet; the resulting wave curves were recorded by photography with an ordinary camera. The exposure required was of the order of 10 mins., and in order to shorten this time Zenneck tried to get a brighter spot on his screen by faster running of the electrostatic machine that supplied the tube. This led to a troublesome unsteadiness of the discharge and flickering of the ray. This was

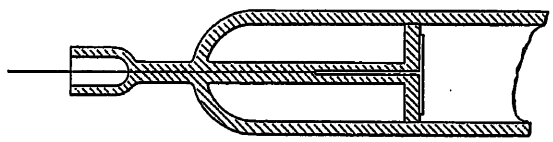

FIG. 17.—Zenneck's cathode.

largely remedied by the use of an insulating backing to the cathode as shown.

Milham † in 1901 used a tube made by Müller-Uri to Zenneck's design for measuring electric fields (between external deflecting plates), but trouble was experienced with obtaining a steady electrostatic deflection of the jet "due to ionization of the residual gas."

In 1902 one of the present authors ‡ designed a

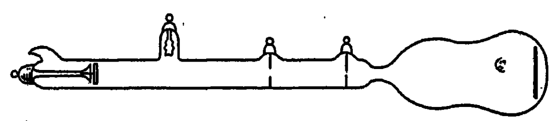

FIG. 18.—Cossor tube.

modification of Prof. Braun's apparatus, and demonstrated its use for the determination of the maximum value of an alternating current. This tube incorporated Zenneck's improvements, including a cathode with a glass shield, and was smaller and therefore more compact than the original tube; it was manufactured by Cossor (see Fig. 18).

In 1903 Ryan § reported his work on wave-forms using the cathode-ray tube on the cyclographic method.

* See Bibliography, (75 and 76). † *Ibid.*, (68 and 69).

* See Bibliography, (77). † *Ibid.*, (78). ‡ *Ibid.*, (1). § *Ibid.*, (79).

He had "found that the tubes on the market were altogether too small to be of practical use." He required the fluorescent screen of double the size (i.e. 6 in.) and in 1900 after many trials Müller-Uri of Braunschweig succeeded in delivering two tubes with screens .5 in. diam. (see Fig. 19). These large tubes proved unsatisfactory at the outset, giving an intermittent cathode-ray jet; this trouble was traced to corona and external leakage of the high-tension supply, and was overcome by a thick jacket of solid insulation (ebonite discs sealed on with paraffin wax, surrounding the cathode end of the tube). The trouble would probably have been avoided by making the tubes with an extended glass neck at each electrode, as is the practice with X-ray tubes.

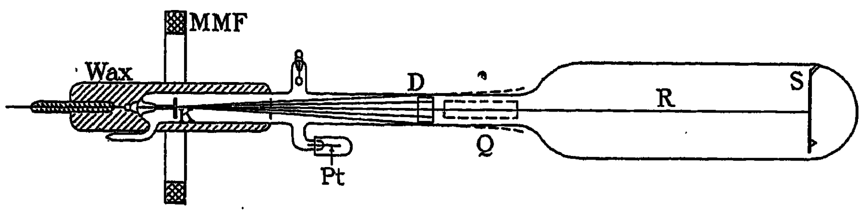

FIG. 19.—Müller-Uri tube used by Ryan.

Rankin * in 1905 used a Müller-Uri tube similar to that used by Ryan. The tube was fitted with an osmosis vacuum regulator, to enable the vacuum to be softened and so avoid the use of too high a P.D. on the tube which results in flickering of the jet. The tube was worked with a P.D. of from 17½ to 20 kV. Rankin also investigated the effects of using a "concentrating coil" with the tube.

In 1911 Ryan † reported further use of the large Müller-Uri tube, operating on an excitation of 10 kV. Successful use was made of external condenser plates for producing electrostatic deflection of the electron jet for both components, the apparatus being used as a cyclograph. This is the first use of the electron-jet instrument for measuring power losses in high-tension circuits.

Roschansky ‡ in 1911 experienced a flickering of the jet in the cold-cathode tube when driven with a high P.D. He was studying the oscillatory spark discharges of a condenser, and since these involved high-frequency variables it was essential to have a steady jet. Roschansky traced the trouble to the region of the exhausted tube behind the cathode disc, as Zenneck had done, and filled this space with crumpled tin-foil held in place by a metal screen (as shown in Fig. 21). He also introduced the tubular type of anode (serving also as diaphragm, like Zenneck's arrangement).

Roschansky used in his tube, for the first time since J. J. Thomson's experiments, electrostatic deflecting plates mounted inside the vacuum; these were shielded at each end with diaphragms having holes large enough to allow passage of the deflected jet. The axial focusing coil was also used (see Fig. 20).

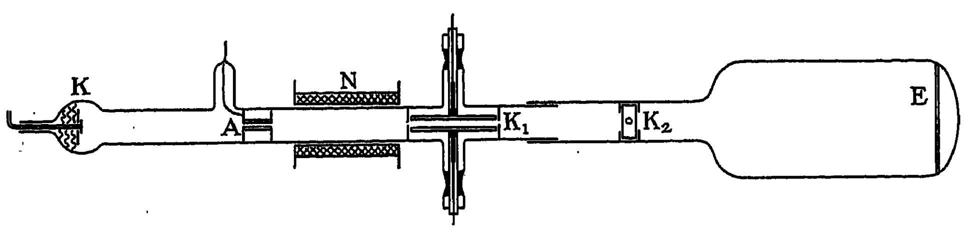

FIG. 20.—Roschansky's tube

For his work on the spark excitation of "undamped" waves Chaffee * (1911) imported Müller-Uri tubes from Germany. These, however, he altered, inserting a ring anode and substituting a glass diaphragm in the form of a truncated cone, having a hole about ½ mm diam. Condenser plates for electrostatic deflection were also mounted inside the tube. The tube was kept connected to a pump, and the best condition of vacuum was that which gave a ray bundle about 1 mm in diameter at the cathode. Excitation was at 29 kV.

Minton † (1915) found that the tubes on the market that had been developed and used by previous investigators (see Fig. 22) were not satisfactory for his purpose,

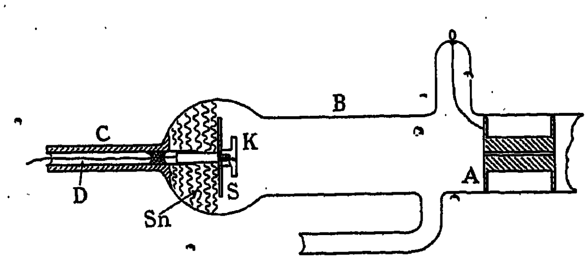

FIG. 21.—Roschansky's cathode and anode.

which was to develop a method of testing that was suitable for commercial routine, together with appropriate apparatus that would be sufficiently constant and dependable, "ready for use at any time, just like a galvanometer is." In this connection steadiness of

* See Bibliography (80 and 81). † *Ibid.*, (82). ‡ *Ibid.*, (83).

* See Bibliography, (84). † *Ibid.* (85 and 86).

vacuum conditions is one of the essential factors. Some workers had obtained this by prolonged baking of the tube while on the exhausting pump, but tubes so treated showed the flickering of the jet to a greater extent than before.

Ryan (1908) had found external discharges and eliminated them by a jacket of solid insulation, and Rankin (1905) had used a tube with an osmosis regulator which eliminated the necessity for using an excessive exciting P.D. However, Zenneck (1899) had discovered that discharges took place inside his tube, apparently between the cathode and the glass. To avoid this the cathode was set in a close-fitting glass sheath; but Minton found the trouble still present with this arrangement. Again, Roschansky in 1911 had tried to eliminate the trouble with tin-foil leaves that would conduct away the charges.

Minton found that his early tubes, which, due to lack of careful exhaustion, tended to soften (in vacuum) with use, were free from this defect. Evidently the film of adsorbed gas which remained on the glass surface of such tubes constituted a sufficient leak for the charges that accumulated. It was then found possible by means of a proper adjustment of the heat treatment given to the tubes during exhaustion (i.e. ½ hour at 350° C.) to effect a satisfactory compromise, "thus attaining steadiness of vacuum for several hours' continuous heavy operation, while leaving on the glass sufficient gas film to conduct away the charges."

In 1914 Dufour * proposed using the electron-jet instrument for recording extremely rapid transient phenomena, and pointed out the necessity of developing an instrument sufficiently powerful to produce the required permanent trace with a single transit of the jet across the recording plate, and showed how high the velocity of this transit may be expected to be (up to 3 km per sec.).

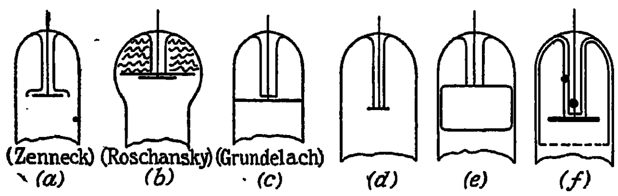

FIG. 22.—Comparison of cathodes (after Minton).

In 1918 Dufour described his first apparatus designed to carry out this idea (see Fig. 23). In his discharge tube for producing the electron jet there was no radical departure from the practice of his predecessors. However, liberal length was allowed, for the glass stem supporting the cathode, for the discharge volume (between cathode and anode), and for the anode itself, which was tubular and carried a diaphragm at each end.

The apparatus was kept connected to the vacuum pump, and the gas pressure correctly adjusted—on the one hand to take advantage of the high P.D. to secure a fine and intense trace, and on the other hand to prevent the occurrence of discontinuity of the discharge (giving a flickering jet) and brush discharges on the external conductors.

* See Bibliography, (87, 88 and 89).

In 1922 Dufour described an attempt at a "double" instrument. In this apparatus there are two similar discharge tubes, each complete with anode-diaphragm, mounted in inclined positions on the two branches of a Y-tube (see Fig. 24). The two electron jets produced are first separately acted upon by their respective deflecting fields, then, further on in their paths, when they have approached each other fairly closely, they are turned into parallel directions by small electromagnets. The two discharge tubes are found to function simultaneously when a liquid resistance is connected in series with each cathode. Experience shows, however, that the operating conditions will never be identical in the two discharge tubes, and the resulting inequality of the sensitivity of the two rays renders it impracticable to use a double instrument for high-frequency work, in which the jets must respond to a number of auxiliary deflecting fields.

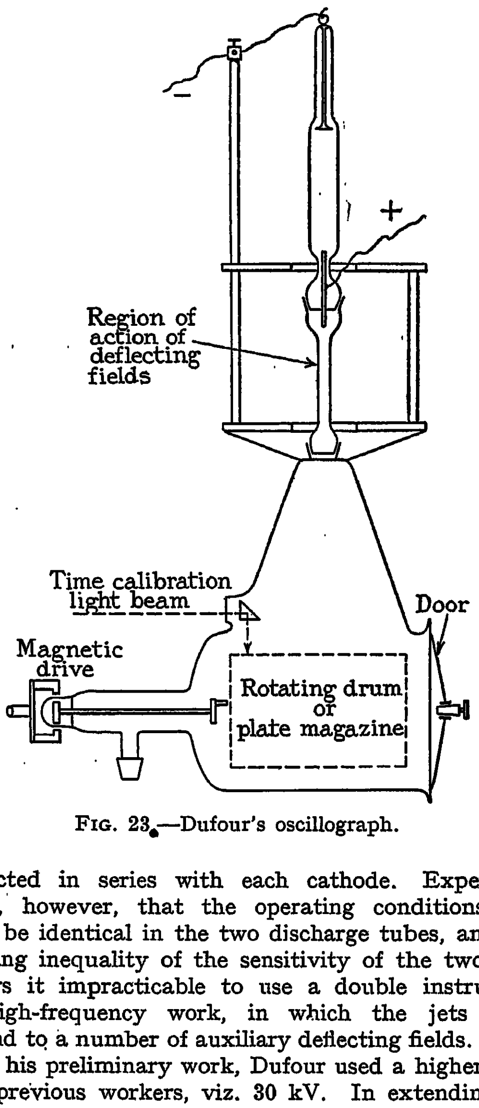

FIG. 23.—Dufour's oscillograph.

For his preliminary work, Dufour used a higher P.D. than previous workers, viz. 30 kV. In extending the frequency range of his oscillograph, however, it was necessary to increase this up to 60 kV, giving an increased intensity of jet that would compensate for the higher velocity of traversal across the photographic plate. However, at the highest frequencies tried a definite limit was found—not because of insufficient power in the jet to give a readable record with the high velocity of traversal, but because of too great an

intensity. For with the cold-cathode discharge the current carried by the jet increases faster than its velocity, hence with increased power on the tube the electron density increases, and this gives rise to increased "scattering" of the jet (see Appendix B, 5), and a point is reached where the blurring and faintness of the trace due to this cause more than counterbalances the gain due to the increased velocity of and current in the jet.

Hull * (1921) concluded that the flickering troubles associated with charging of the internal surface of the glass were due to the influence machine largely used by previous investigators for exciting the cold-cathode instrument, and found that the difficulty was reduced to a minimum by using a steady source of high-tension power, such that earthing the anode and also an electrostatic shield surrounding the tube in the neighbourhood of the screen were sufficient to stabilize the conditions of discharge and electron flow down the tube. The high-tension supply was derived from a step-up transformer running on alternating current and two Kenotron (diode) rectifiers, and was taken through a smoothing circuit (consisting of two 0·04 μF condensers and a 5H inductance, with the π-connection). The arrangement was thus little different from Minton's, who used a mechanical (rotary commutator) rectifier, and a plain stabilizing resistance instead of a smoothing circuit.

Hull used a polished concave cathode having a radius of curvature somewhat less than the distance to the screen (see Section VI, C, 2), and a diaphragm with a very fine hole 0·01 in. diam. (see Fig. 25). The diaphragm was made in two parts, with a shielded opening round the outer edge to allow free passage of gas during exhaustion. The tube was baked at 350° to 400° C. in an electric furnace while connected to the pump, the optimum point being reached with the dark space extending 0·2 to 1·2 in. from the cathode, corresponding to a gas pressure of from 4 to 13 millionths of an atmosphere. With an applied P.D. of 10 kV the current was 50 to 500 μA.

(V) THE HOT-CATHODE INSTRUMENT.

(A) WITH "LIME-SPOT" CATHODE.

The first electron-jet apparatus to incorporate a "hot cathode" (i.e. using thermionic emission to stimulate the discharge) was that of Wehnelt * (1905); this has already been described [Section III, C, 4, (b)]. The outstanding advantages gained by the use of this apparatus are the production of a very intense electron jet (due to the heavy electron emission from the hot lime) combined with a much greater sensitivity to deflection (due to the low jet velocity).

About 1909 A. G. Warren, F. Murphy and one of the authors worked in the same direction. A standard Braun-Wehnelt apparatus was first tried, but had soon to be abandoned as it proved incapable of giving consistent results. The chief experimental difficulty encountered was "clean up" or hardening of the vacuum (reduction of gas pressure) taking place simultaneously with the discharge. As a result of this the cathode emission diminished, thus further emphasizing the loss of positive ionization, so that

* See Bibliography, (90).

* See Bibliography, (74).

the instrument rapidly became unworkable. It was found that if any reasonable constancy of emission was to be obtained, it was necessary to keep the gas pressure constant and as low as possible, obtaining the necessary emission by coating the cathode. Further than this, the emission was found to be determined chiefly by the physical condition of the electrodes rather than the controllable variables mentioned above. In fact it has been more recently established by Ratner * that the gas which functions in these phenomena is not so much the free gas in the apparatus as the adsorbed gas and the absorbed gas.

Subsequently a new apparatus was built, designed to be kept connected to the vacuum pump (see Fig. 26). It was found necessary to make the cathode adjustable, so that the platinum strip carrying the lime spot could be tilted both horizontally and vertically. Dr. Willows kindly assisted these investigators in the technique of producing the lime-spot cathode. Also the fluorescent layer was carried on the inner surface of a cover plate which closed the large bulb of the apparatus (with a ground joint). It was thus possible to renew the active material when it became fatigued. A reasonable "spot" was obtained which did not break up on deflection. Unfortunately at this promising stage the work had to be left.

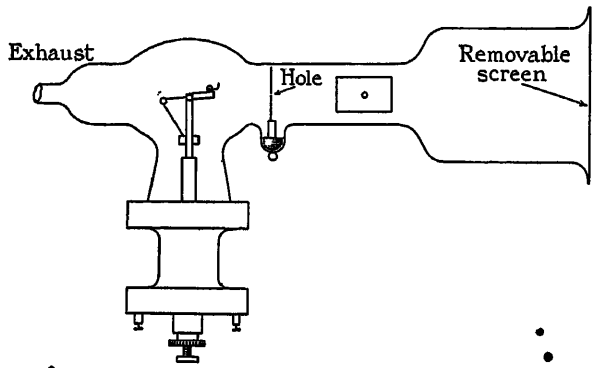

FIG. 26.—Apparatus of Morris, Warren, and Murphy.

Willows and Picton † (1910) investigated the Wehnelt type of cathode, its behaviour under different conditions of operation, and its alteration with time. Lime heated on platinum foil showed not fatigue but on the contrary a considerable increase in activity, up to ninefold with P.D.'s greater than the saturation value, and up to twofold with lower P.D.'s. When heated on nickel foil the lime showed an increase in activity to a maximum, followed by a decrease, with the higher P.D.'s; with the lower P.D.'s its behaviour was similar to that with platinum. No connection could be determined between the activity and the quantity of electricity passed. On first starting a discharge great irregularity was shown; other causes than temperature, such as mechanical vibration, greatly influenced the emission of ions.

The lime coatings used in these experiments were examined under the microscope, and were found to be very adherent to the platinum—in fact it was impossible to free the platinum again from the activity with which the lime endowed it. This effect was attributed to diffusion of the lime into the platinum.

Knipp and Welo * (1915) used an electron jet instrument (see Fig. 27) as a magnetometer for measuring the earth's field. To obtain the necessary sensitivity a hot cathode of the Wehnelt type was used. Records were obtained by direct registration of the jet on a photographic plate mounted in the vacuum chamber (see Section VII, B); and although the photographs show the width of the spot to average about 10 per cent of the deflection, an accuracy of measurement to within 0·3 per cent was claimed on an average of seven readings.

An additional reason for the use of a lime-spot cathode for this work was the necessity for obtaining a definite jet of sufficient range without the use of diaphragms (since the whole instrument is immersed in the "deflecting field"); this was found possible when the spot of lime (ignited sealing wax) did not exceed 0·02 cm (8 mils) in diameter. The cathode was mounted on a double ground joint (see Fig. 28) permitting adjustment (tilting) in two directions—the two adjustments were found necessary for producing a well-defined indicator; this was usually a drawn-out band 2 or 3 cm in length (in the plane of the platinum strip). In passing between the two electrostatic deflecting plates mounted in the apparatus the stream of electrons was not narrow, but spread out, and only a bluish glow was visible. Beyond the plates, however, two converging streams could be seen, these generally crossing at the further end of the tube. The position of crossing depended on the heating current supplied to the cathode, frequently more than one value being found which would give a satisfactory result; the lower temperature was usually chosen.

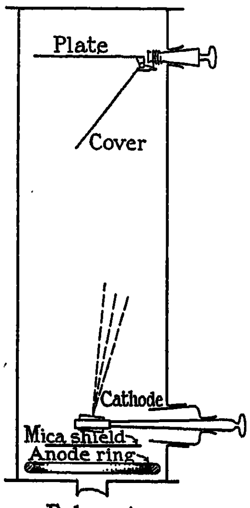

FIG. 27.—Apparatus of Knipp and Welo (general arrangement).

The above-described behaviour of the discharge indicates strongly the presence of an "ionic focusing effect," similar in principle to that developed by

* See Bibliography, (91). † Ibid., (92).

* See Bibliography, (93 and 94).

Johnson (see Section VI, C, 2). The exhaustion of the tube was assisted with a charcoal trap immersed in liquid air. The gas pressure actually used in making measurements is not given, but the statement is made that the Wehnelt cathode ceases to act if the pressure is less than about one millionth of an atmosphere. It

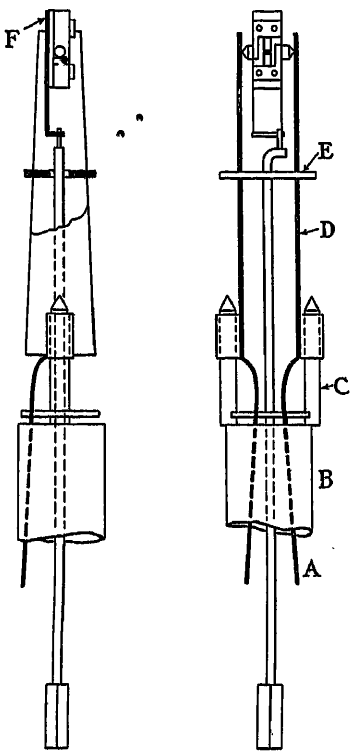

FIG. 28.—Adjustable lime-spot cathode used by Knipp and Welo.

was found best to renew the lime for each exposure, and, owing to the difficulty of mounting a new spot of such small size immediately over the old one, the platinum strip had to be renewed also. In both the preliminary and the final forms of the apparatus the anode was mounted behind the cathode, and the successful working obtained with this arrangement demonstrated clearly the important part played by the fall of potential at the cathode in accelerating the electrons. The total P.D. applied to the apparatus was from 800 to 1 000 volts.

Crooker * (1918) constructed an instrument on lines similar to the foregoing (see Fig. 29). The cathode was a gimbal-mounted platinum strip carrying a lime spot; the lime used for this was mixed with a little barium nitrate to facilitate application as a paste, and to ensure a longer life. The anode was annular in form and mounted quite close (about 1 cm) in front of the cathode; in addition it was found necessary to use a diaphragm (which was placed beyond the magnetic deflecting field) to cut off extraneous light from the hot cathode strip, and also to stop down the divergent jet. The P.D. used to operate the instrument was 300 to 400 volts, and it was found advisable to have the fluorescent screen as close to the cathode as was consistent with the sensitivity required of the apparatus.

It was necessary to maintain a very low gas pressure, exhaustion being assisted with charcoal in liquid air. The hot lime cathode gives off gases quite freely, necessitating constant pumping if the instrument is to be used for any length of time.

(B) WITH BARE TUNGSTEN FILAMENT.

Coolidge * (1913) demonstrated the practicability of using a pure electronic discharge, producing, in fact, cathode rays in his hot-cathode X-ray tube. The hot cathode (see Fig. 30) was an electrically heated filament, made from tungsten wire 0·216 mm diam., closely wound into a flat spiral and mounted inside a coaxial focusing hood (see Section VI, D, 3) whose bore was 6·3 mm. With an input of 23 watts for heating, the temperature attained was 2 540° absolute, and the emission current (constituting also the discharge current) was 40 mA.

Samson † (1918) applied the principle to the electron-jet instrument. His hot filament was made also of tungsten wire (0·2 mm diam.), wound spirally and mounted in a hood, and the maximum emission current obtained was about 10 mA. The first instrument constructed (see Fig. 31) was kept connected to the vacuum pump, and exhaustion was continued until an 8-inch spark coil failed to pass a discharge (with the cathode cold). The instrument was equipped with an aluminium diaphragm 2 mm thick and having a 1-mm diam. hole; this served also as anode. The accelerating P.D. used varied from 1·5 to 9 kV, and an axial coil was used to help to "focus" the jet.

The second instrument built (see Figs. 32 and 33) was sealed off and hence portable; exhaustion lasted for 10 hours, during which time the whole apparatus was baked at 365° C., the filament also being kept glowing. When

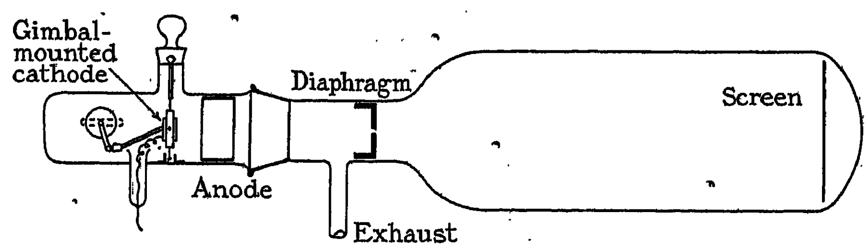

FIG. 29.—Apparatus of Crooker.

* See Bibliography, (95).

* See Bibliography, (75 and 76). † Ibid., (96).

working subsequently the path of the electron jet was absolutely invisible, demonstrating the absence of ionization. In this instrument the diaphragm was placed nearer to the anode (5 cm distant) and was made of nickel on account of its higher melting point. Two condenser plates for electrostatic deflection of the jet were mounted inside the apparatus; two diaphragms

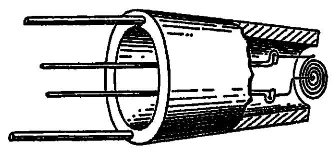

FIG. 30.—Coolidge's hot cathode.

were placed one at each end of these plates, with holes 8 and 10 mm diam. respectively, in order to prevent the emission of "secondary electrons." In this case also a focusing coil (of 500 ampere-turns) was used, placed in the plane of the anode; the fluorescent screen showed a bright blue spot 5 mm diam.

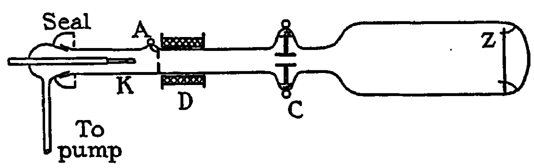

FIG. 31.—Samson's first tube.

Lübcke * (1918) also used a bare tungsten filament, but it was wound into a helix, instead of a flat spiral; it was mounted with its axis perpendicular to that of the tube, and no focusing hood was fitted. A single diaphragm, about 15 cm distant from the filament, served also as anode. Different jet velocities were

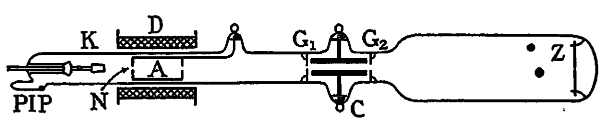

FIG. 32.—Samson's portable tube.

used, the accelerating P.D. covering a range of from 220 to 23 000 volts.

Keys † (1921) also used a hot cathode of the Coolidge type. The other important features of his instrument (see Fig. 34) were a fine axial tube in place of a fine

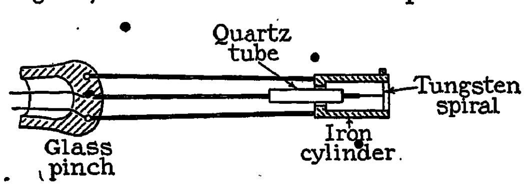

FIG. 33.—Samson's hot cathode.

hole in the diaphragm-anode, and a guard tube extending round the electrostatic deflecting plates and beyond to the metal chamber housing the photographic plate (in the vacuum). This chamber and the guard tube were connected to the anode and earthed. Focusing of the spot was secured by adjustment of the accelerating P.D. (normal value 5 kV), and by axial rotation of the cathode, which was mounted on a ground stopper for the purpose.

Wood * (1923) built an instrument on the same lines as that used by Keys. After trying different arrangements of filament, hood and anode with a view to solving the focusing problem (see also Section VI), the Coolidge type of cathode and the fine tubular anode were adopted. A plain tungsten filament was first used, but a filament of the coated type was preferred.

Wood developed his instruments into a robust form,

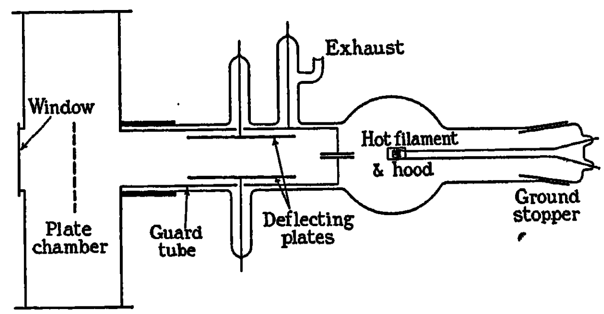

FIG. 34.—Keys's oscillograph.

suitable for use in workshop rather than laboratory. It was built of metal except for a glass drying bulb and the glass mounting to insulate the cathode; it was arranged so that it could be dismantled in a minimum of time, by means of ground joints. Permanent connection to the vacuum pump was necessary, since records were made on a photographic plate placed inside the vacuum.

(C) WITH COATED FILAMENT.

For his first hot-cathode instrument (see Fig. [35), Hull † (1921) made use of the screen and bulb of the Müller-Uri cold-cathode instrument. The anode was in

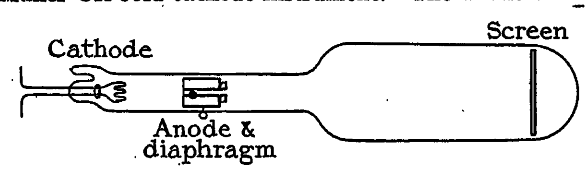

FIG. 35.—Hull's hot-cathode tube.

the form of a ring, fitting the glass tube closely, and the cathode, a platinum strip 1 mm wide carrying a deposit of Wehnelt oxides "the size of a pin's head" was fixed in position. No filtering diaphragm was used, the idea being to rely upon a powerful focusing coil of 500 ampere-turns and the limited size of the emitting surface for obtaining a fine spot [see also Knipp and Welo (1916), and Crooker (1918), Section V, A].

In later instruments, however, a diaphragm was used, with a 0·01-in. hole, similar to that used in his cold-cathode instruments (Section IV). With an accelerating P.D. of 500 volts, the spot obtained was

* Extracted from a Report to the British Electrical and Allied Industries Research Association.

1 mm diam. Further, the cathode used was a W-shaped platinum wire, coated over its whole surface with barium oxide or calcium oxide (lime).

In these instruments, both types using the Wehnelt oxide cathode, the gas pressure was reduced to its lowest limit, thus eliminating ionization. Hull states that the most important advantage of the coated type of filament for use in the electron-jet instrument is the smaller amount of light emitted, combined with a bountiful supply of electrons.

In the hot-cathode instrument developed by Johnson * (1921) the cathode (see Figs. 36 and 37) is a short platinum ribbon bent into a circle, with an oxide coating of the kind described by Arnold † (1920).

Due to the presence of gas (argon at about 10 millionths of an atmosphere) employed for a special method of focusing (see Section VI, C, 2), precautions have to be taken against the development of an arc discharge. To achieve this the electrodes are enclosed in a glass mounting of small volume (1 cm^3); by this means all the paths between the electrodes are made so short that the ionization cannot build up to an excessive amount. As a further precaution a stabilizing resistance (of a few thousand ohms) is connected in the anode circuit. Further, positive ion bombardment is found to destroy the activity of the oxide coating on the cathode very rapidly; to minimize this a metal shield is placed in front of the filament, this latter being shaped into a loop so that it lies just behind the edge of the hole cut in the shield. The filament is thus protected from the "direct" bombardment and its average life is extended to about 200 hours.

The anode used is tubular, with a bore of 1 mm and a length of 1 cm; its inner end approaches within ½ mm of the shield in front of the filament, and it forms the only outlet from the confined electrode chamber to the rest of the apparatus; the electrons therefore are shot out along the bore of the anode to form the jet—hence the name "electron gun" applied to the electrode assembly.

Two pairs of deflecting plates are provided, and these are made of german silver to reduce eddy-current effects should it be desired to use magnetic deflection. Again, owing to the gas present, and the ionization caused by the jet, these plates pick up certain amounts of the discharge current, varying according to their potential with respect to the anode; the instrument thus constitutes a load of varying amount on the circuit on which measurements are being made, and in certain cases this may be a serious drawback.

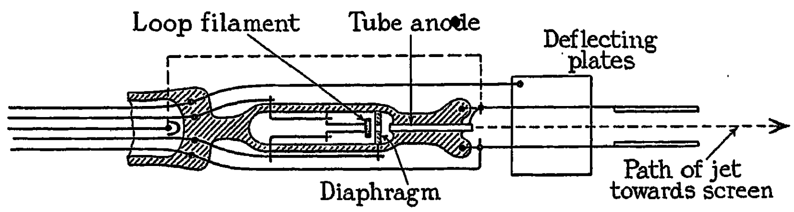

FIG. 36.—Electron gun of Johnson's tube.

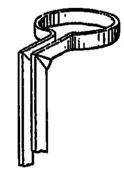

FIG. 37.—Coated platinum filament of Johnson's tube.

Jones and Tasker * (1924) developed an instrument having an arrangement of electrodes (see Fig. 38) similar to that of Johnson, except that it was not necessary to mount them in a confined space (mercury vapour at a lower pressure, about 3 millionths of an atmosphere, was used in place of argon).

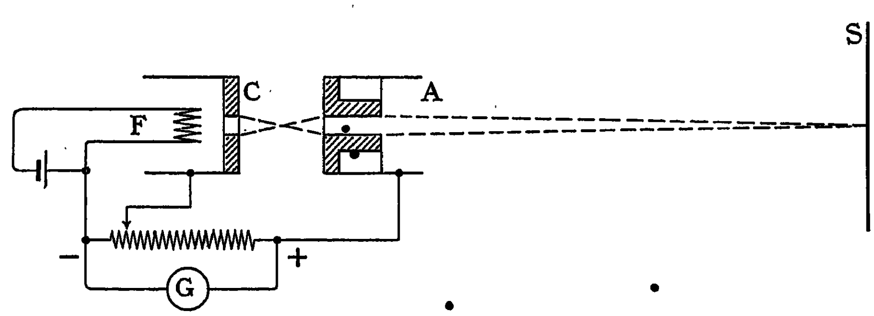

FIG. 38.—Electrode arrangement of Jones and Tasker.

The operation of the instrument was different, however, in that an auxiliary P.D. was applied between the filament and the disc in front of it; this is stated to produce "secondary electrons," formed at or near the surface of the cathode disc, the jet being drawn from these. It appears, in fact, that this disc receives most of the positive ion bombardment, since it shows signs of disintegration after prolonged use, while the oxide coating on the filament functions unimpaired. The method also gives an improved control of the focus on the jet (see Section VI, C, 2).

* See Bibliography, (100 and 101). † *Ibid.*, (102).

* See Bibliography, (103.

(VI) METHODS OF "FOCUSING" THE ELECTRON JET.

(A) INTRODUCTORY.

(1) THE NEED FOR FOCUSING DEVICES.

It will be gathered from Section I that an essential condition for the accurate working of an oscillograph or a cyclograph is that the "indicator" shall be of minimum size consistent with its visibility, or its ability to trace a record. In the case of the electron-jet instrument this means that the jet must be of as small a diameter as possible at the point where it strikes the fluorescent screen or photographic plate (see Section VII) and moreover its boundaries must be definite so that the trace made shall be sharp and clear. Needless to say this condition should be affected as little as possible by either the displacement or the velocity of the jet's deflections, within the normal working limits. Unfortunately the following causes tend to produce just the opposite condition :—

(i) The devices used for producing the electron jet (involving essentially the "source of electrons" and the "accelerating field") may not be perfect in their action, in so far as the motion given to the electrons may not be properly parallel (or convergent, see later), so that the jet commences to disperse at the commencement of its journey.

(ii) Owing to the electrons composing the jet being charged with electricity of the same sign, there is a repulsive force acting between each electron and every other. The radial component of this force is unbalanced and acts outwards (see Appendix, Section XI, B, 5); and since the jet works in a vacuum the electrons are in general free to move radially in response to this force.

(iii) In instruments using a gaseous discharge, there are bound to be collisions (not necessarily producing ionization) between the moving electrons and the molecules of gas in the space traversed; as a result the electrons will be deflected from their original courses, some more and some less, so that not only does the jet grow in diameter but it also becomes diffuse, producing a blurred trace with indefinite boundaries (see also Section III, C, 5).

(2) THE HIGH-VELOCITY JET.

In the early electron-jet instruments, developed by J. J. Thomson, Braun, and Zenneck (see Sections III, B, and IV), it was found experimentally that to produce a satisfactory jet it was necessary to use a high exhaustion and a high P.D. The explanation is to be found in the second and third causes described above. For, on the one count, the absorption of the rays is reduced by lowering the pressure of the residual gas in the apparatus; and on the other count, with a higher accelerating P.D. the velocity of the jet is higher and the time of flight of the electrons from source to screen is shorter, giving less dispersion due to the force of mutual repulsion.

The work of Dufour may also be quoted as an instance of the use of a high P.D. (up to 60 kV), though it should be stated that this value was chiefly necessitated by the requirements of recording (Section VII); the oscillograms taken with his instrument show a remarkably fine and sharp trace. The same tendency may be noted with the hot-cathode instruments (Section V).

It should be noted that even the high-velocity method fails if other factors are not prevented from influencing the behaviour of the jet. Thus Dufour (see Section IV) in trials of this oscillograph at very high frequencies (up to 220×10^6 cycles per sec.) found that increase of power beyond a certain point *decreased* the sharpness of the trace, by causing the jet to disperse, due to the increased *electron density* in the jet (see also Section XI, B, 5).

(B) ELECTROMAGNETIC METHODS.

(1) USE OF THE AXIAL FOCUSING COIL.

Other workers, however, found that even with these precautions there was still much to be desired, not merely in the size of the spot indicator, but in its intensity and sharpness. Wiechert (1898) and others * found that by applying a fairly strong magnetic field to the jet instrument parallel to its axis, the spot could be concentrated into a smaller area.

Rankin † (1905) studied the effect with the instrument designed by Ryan (see Section IV) and confirmed what others had found, viz. that application of the longitudinal field produced a large but irregular decrease in the P.D. required to produce a discharge, whilst the current passed through the apparatus was substantially unaltered. Thus by use of this focusing field it was possible to exert a large measure of control over the sensitivity of the instrument. Owing largely to its simplicity this method of focusing became standard practice with most of the workers using cold-cathode instruments.‡ The usual method of applying the field is by means of a short solenoid coil, 6 in. or more in diameter, mounted axially with the jet instrument either in the plane of its cathode or between the cathode and the diaphragm. Two coils have been tried in place of one (see also Hull, 1921); the only advantage is to lessen the tedium of adjustment of position, orientation and current strength (a range of 500 to 2 000 ampere-turns was found satisfactory).

(2) MODE OF OPERATION.

The effect of the axial focusing coil is to immerse the electron jet in a longitudinal magnetic field. Thus if the electrons are moving properly parallel, the field exerts no deflecting force on them; but if there is any divergence in the jet, the electrons will have a component of motion perpendicular to the direction of the field, and a deflecting force will result (see Fig. 39).

Suppose an electron to acquire a direction of motion inclined at an angle θ to the direction of the field. If the field is assumed uniform and parallel, and of strength H, then the perpendicular component of the electron's velocity is

$$v \tan \theta,$$

* See Bibliography, (104, 105 and 106). † *Ibid.*, (80 and 81).
‡ *Ibid.*, (82, 85, 90 and 107).

and in the Appendix it is shown to be subject to an acceleration

$$\frac{Hev \tan\theta}{m_t}$$

Now this acceleration is always perpendicular to the transverse velocity at each instant, so that the transverse motion becomes circular, the resultant motion of the electron being a helix.

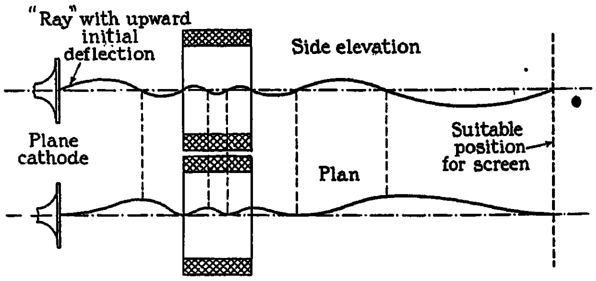

FIG. 39.—Path of electron jet with axial focusing coil.

The acceleration due to the field must obviously be equal to

$$\frac{(v \tan\theta)^2}{r}$$

where r is the radius of the component circle,

whence $$r = (v \tan\theta)^2 \times \frac{m_t}{Hev \tan\theta}$$

$$= v \tan\theta \frac{m_t}{He}$$

The component velocity in the circle, $v \tan\theta$, remains constant because the acceleration is always perpendicular to it; hence the time taken to make one revolution is

$$t = \frac{2\pi r}{v \tan\theta} = 2\pi\frac{m_t}{He}$$

and, from this, the "pitch" of the helix is

$$s = 2\pi\frac{m_t}{He}v$$

Thus after travelling an axial distance equal to this quantity, the electron reaches again the same position relative to the axis of the apparatus as that from which it started. The important point to note is that this axial distance is independent of the angle of divergence, θ.

The effect of non-uniformity of the magnetic field, such as is produced by a single focusing coil, is to cause a varying angle of helix; but the property of focusing all electrons, though of different degrees of divergence, is unimpaired. It is, in fact, possible by means of such a non-uniform field to produce a spot on the screen smaller in size than the diaphragm hole.

(3) AXIAL CONDUCTOR METHOD.

It seemed desirable to improve on the indirectness of the focusing-coil method, and to provide some means whereby the electrons might be deflected directly in a radial direction. To achieve this object a method (see Fig. 40) was devised by F. R. F. Ramsay (1923) and has been subjected to some preliminary trials by the authors at East London College.

The principle is the use of a circular magnetic field concentric with the jet; to produce this, a straight conductor is mounted in the axis of the instrument (along the undeflected position of the jet); current is led into and out of this conductor at its ends by a number of flat radial strips, and the jet is thus able to pass over the conductor close to its surface (where the field is strongest) with minimum obstruction.

When the electron flow is in the same direction in the axial conductor as it is in the jet, then the circular field is in the correct sense for exerting an inward radial force on the jet electrons, i.e. for producing a focusing effect. A disadvantage of the method is that the strength of the field, and therefore the focusing force on each electron, is inversely proportional to the distance from the conductor (axis), whereas in general the further an electron is from the axis the larger is the radial force that it requires (see also Appendix).

(C) ELECTROSTATIC METHODS.

(1) RADIAL FIELD.

Attempts have been made to focus the jet of a cold-cathode instrument by electrostatic means. The tubular portion (both sides of the anode) was provided with tin-foil coatings and these were connected to the cathode, so that there should be a mutual radial repulsion between the coating and the jet electrons. The method naturally failed, because the "potential" of an electron, when unconstrained as it is inside the vacuum, becomes that of the space in which it is situated. To explain this it should be remembered that "potential" means "potential energy," and, since an unconstrained charged body can possess no potential energy, the energy supplied by the field in space appears as a change of kinetic energy. In other words we have the conditions that *radially* there is no electric field inside the hollow conducting coating, and *axially* the field retards the electrons and brings them to rest after they have been projected by the cathode fall of potential. Connection of the coating to the anode (positive electrode) did produce an improvement in the "spot."

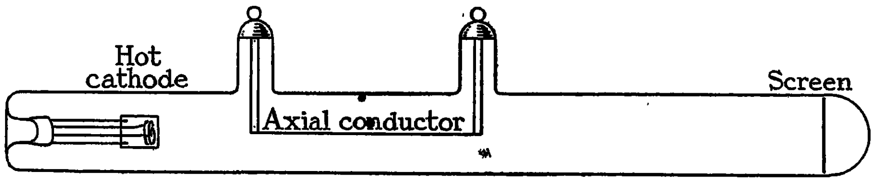

FIG. 40.—Electromagnetic focusing with axial conductor.

A correctly applied modification of this method was tried with his hot-cathode instrument by Wood * (1923, see Fig. 41). A tubular anode was used, arranged axially in the instrument, and along its axis was fixed a wire, which was charged positively with respect to the anode tube. The electrons passed along inside the anode tube. The *axial* effect of the positively charged wire was to accelerate them rather than to retard them, and the *radial* effect was to produce a radial electric

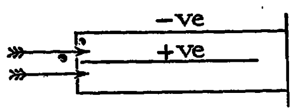

FIG. 41.—Electrostatic focusing with positively-charged axial conductor (after Wood).

field which exerted a definite focusing influence on the jet. However, on this particular instrument the method was not so satisfactory as the one finally adopted (see Section VI, D).

(2) "IONIC" METHOD.

(*a*) *Mode of operation.*

Johnson † (1922) has successfully applied a neat method of focusing, which he states was originally suggested by van der Bijl. The method appears to be a scientific development of an effect which has been more or less operative in all the hot-cathode instruments working with a very low P.D. (mostly using Wehnelt type cathodes), as described in Section V. The instrument is filled with gas (preferably of a heavy nature, see later) at a definite pressure, approximately 10 millionths of an atmosphere. As a result a small proportion of the electrons in the jet collide with molecules of the gas and ionize them. Owing to the large difference between the mobilities of the electrons and of the positive ions (especially with a heavy gas), the colliding electrons and any secondary electrons produced mostly leave the jet, whereas the positive ions drift out only slowly, with little more than their comparatively low thermal velocity. The positive ions therefore tend to accumulate down the length of the jet, and a point can be reached where the number of positive ions in the jet considerably exceeds the number of electrons therein. The jet thus becomes positively charged with respect to the surrounding gas and the glass walls of the instrument, and there is established a strong radial field of the correct sense to exert an inward radial force on the electrons within the jet.

At the point where the positive ions and the electrons are equal in numbers, the mutual repulsion of the electrons is just neutralized; and with the positive ions in excess of the electrons a definite focusing effect is obtained. Johnson calculates that if in his instrument the jet has an initial divergence of 1°, and carries a current of $20\mu A$, the jet will be focused at the screen when there are four positive ions in the jet to each electron, giving a radial field of 1 volt/cm. Measurements in a special apparatus with one jet perpendicular to another gave a value for this radial field of 3 volts/cm.

* See Bibliography, (99). † *Ibid.*, (101).

(*b*) *Advantages and limitations.*

The great advantage of this focusing method is the fact that the action on the jet is continuous throughout its length, not interfering with arrangements for deflection of the jet. It should be noted, however, that there is a definite time factor in the establishment of the positive ionization within the jet, and this leads to the disadvantage that if the jet is deflected too rapidly through the gas space the ionization fails to build up to the proper value, since the ions are produced at points along the jet, and are not travelling longitudinally with the electrons. Thus from the figures given in Johnson's paper the focusing action is found to fail as the "velocity of traversal" of the fluorescent spot reaches 100 km/sec.

An additional convenience is the ease of adjustment of the focusing action, for it is found that variation of the filament temperature, which controls the current in the jet, suffices to control the magnitude of the radial field, and hence the distance along its path at which the jet comes to a focus. Now it is shown in the Appendix that the dispersive force on an electron is

$$\frac{2e}{kv}\gamma\frac{I}{R_0}$$

so that with v, γ, and R_0 constant, the force is proportional to the current I in the jet. Johnson states that increasing the jet current causes the jet to focus in a shorter distance; from this it would appear that the positive ion density in the jet increases at a faster rate than the electron density.

In the apparatus of Jones and Tasker * (1924) the jet is focused twice, once between the cathode and the anode, and again at the screen. This confers a further advantage in the operation of the apparatus, for control of the exciting P.D. (applied between the filament and the cathode disc) varies the position of the first focus, and hence the diameter of the jet as it passes the hole in the anode, and so constitutes a control over the focusing of the spot on the screen, this control being independent of the filament temperature adjustment.

(D) "GEOMETRICAL" METHODS.

(1) CONICAL JET.

The methods described under this heading mostly employ some magnetic or electrostatic principle of operation, but are designated "geometrical" because they depend more on controlling the initial direction of projection of the electrons than on applying deflecting forces to them after their formation into a jet.

For example, Wood † (1923) suggested using as anode a number of fine tubes, mounted symmetrically around the axis of the instrument and pointing towards a common point thereon. With this arrangement the jet is composed of the electrons travelling through these tubes, and hence in convergent directions (see Fig. 42).

A similar idea due to E. B. Wedmore (1923) is to use as anode a hollow cylinder or hollow zone of a cone, partially filled with a concentric solid cylinder or cone so as to leave a thin annular space through which the electrons pass. Thus instead of a thin cylindrical jet,

* See Bibliography, (103). † *Ibid.*, (99).

as in Braun's instrument, or a number of convergent jets as in the method above, the form taken by the jet is that of a thin-walled tube. By suitable choice of the angle of the cone, the jet may be brought to a focus at any desired point along the axis. The chief objects of the device were to render possible the use of focusing methods in which the radial force exerted on the electron is dependent upon its distance from the axis, and to obtain a larger current in the jet.

(2) CONCAVE CATHODE.

A more direct method is the one applied in the earliest days in cold-cathode ("gas") "X-ray tubes" by Crookes (1876) and later by H. Jackson, viz. giving the cathode a smooth concave surface on the side facing the "target." Thus by virtue of the property of "normal emission" [see Sections III, A, 3, (*b*), (ii) and III, A, 2] the electrons are given initial directions converging on the centre of curvature of the cathode surface and, by placing the target rather beyond this point, allowance is made for the natural dispersion of the electrons (Section VI, A) and the target receives the jet while it is of minimum diameter.

This method has been applied to the cold-cathode electron jet instrument by Hull * (1921), while Wood †

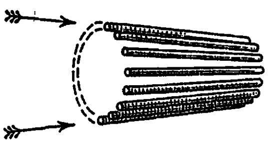

FIG. 42.—Geometrical focusing with inclined tubes (after Wood).

(1923) has suggested using a concave hot cathode, to be kept hot by electron bombardment from an auxiliary cathode. This idea should prove successful if a gaseous discharge is being used for production of the electron jet, for then the "space charge" of the positive ions gives rise to a sudden potential drop at the concave surface of the cathode. If, however, a pure electron discharge is to be used (as was done in Wood's final instrument) the fall of potential occurs at the anode (due to the electronic "space charge") and the concave shape of the cathode surface would not confer so great an advantage as with the gaseous discharge (see also next Section, VI, B, 3).

(3) COOLIDGE'S HOT CATHODE.

A method similar in principle but not dependent on a "cathode fall," and applicable to hot filament cathodes, has been developed primarily by Coolidge ‡ (1913) (see Fig. 30) for his hot-cathode X-ray tube. The filament (of bare tungsten wire) is wound into the form of a flat ("pancake") spiral, and is mounted just inside a cylindrical "hood" to which it is electrically connected, its plane perpendicular to the axes of the hood and the tube. The amount of projection of the hood beyond the spiral filament is found to control the focusing effect produced. In this tube a pure electronic discharge is used, and the "anode fall" due to the space charge is a negligible proportion of the total P.D. owing to

* See Bibliography, (90). † *Ibid.*, (99). ‡ *Ibid.*, (75).

the high values used (up to 100 kV), therefore the axial distribution of potential will be approximately uniform. But, due to the projection of the hood over the filament, the direction of the electrostatic field in the immediate neighbourhood of the filament is strongly convergent, and this determines the initial direction of the electrons; thus although *axially* the electrons are being accelerated approximately uniformly, they retain the inward *radial motion* given to them at the start (see Figs. 43 and 44).* The hot-cathode electron-jet instruments used by Keys † (1921) and Wood ‡ (1923)

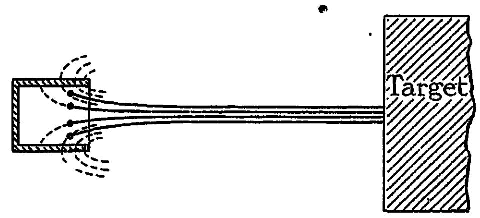

FIG. 43.—"Fine" focus with Coolidge cathode (after Warren).

have Coolidge type cathodes, in conjunction with a "pinhole tube" anode.

(VII) METHODS OF INDICATING AND RECORDING.

(A) WITH FLUORESCENT SCREEN.

(1) VISUAL INDICATION.

(*a*) *Nature of fluorescent material.*

Crookes (1879) and Thomson (1897), we have noted, relied upon the fluorescence of glass for indicating the deflection of the electron jet.

In 1895 Perrin,§ in measuring the charge carried by the rays, used a transverse magnetic field to control

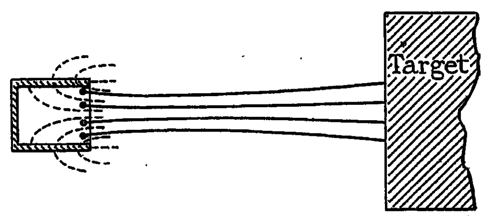

FIG. 44.—"Broad" focus with Coolidge cathode (after Warren).

the entry of the rays into the measuring cylinder (Faraday cylinder); as an independent check the surface of the guard cylinder was coated with a fluorescent powder, and the resulting luminous area indicated the displacement of the rays.

Braun ‖ (1897) was, however, the first to use a fluorescent mineral in an electron-jet measuring instrument. The material he used was willemite (anhydrous crystalline zinc silicate, Zn_2SiO_4) which in his tube showed a bright green colour under bombardment. The material was in the form of a fine powder laid upon a disc of mica which was mounted in the tube as shown (S, Fig. 14).

Zenneck ¶ (1899) made a comparison of the merits

* Also see Bibliography, (108). † *Ibid.*, (97). ‡ *Ibid.*, (99). § *Ibid.*, (46 and 47). ‖ *Ibid.*, (68). ¶ *Ibid.*, (77).

of calcium sulphide and calcium tungstate. Under very intense bombardment CaS gives a fluorescent light which is nearly white, the photographic effect of which is at least equal to that of the blue-purple fluorescence of $CaWO_4$. With weaker bombardment, however, such as that which occurs with average discharge in the cathode-ray tube, or with the fluorescent spot in rapid motion over the screen, the luminous effect of CaS, now a bright green, is still stronger than that of $CaWO_4$, but the photographic effect in much weaker.

Varley * (1902), who used a tube similar to Zenneck's, chose calcium tungstate as the fluorescent material for visual observations.

Morris † (1902) in an English-made tube used zinc silicate for visual work.

In 1909 Giesel and Zenneck ‡ investigated the use of zinc sulphide as a fluorescent material in the Braun tube. This substance gives a blue-green fluorescence, a colour not so powerful visually as the yellow-green of calcium sulphide and zinc silicate; nevertheless the zinc sulphide was found to be more sensitive under the weak bombardment resulting from rapid traversal of the jet over the screen. The substance also gives a distinct afterglow, and this contributes materially to the resultant effect when the jet is tracing a large figure.

Chaffee § (1911) found that a very sensitive screen for visual work could be made by dusting finely powdered willemite over a piece of mica or glass freshly painted with a thin coat of waterglass, but for photographic recording he used zinc sulphide.

Minton ‖ (1915), Hull ¶ (1921), Johnson ** (1922), and Wood †† (1923) recommend zinc silicate (Zn_2SiO_4) for visual work, since it gives a bright green colour, and calcium tungstate ($CaWO_4$) for photography since its blue fluorescence is rich in actinic rays. Johnson in his hot-cathode instrument uses a mixture of half of each, thus combining their advantages and obtaining a fluorescent layer more than half as bright visually as plain zinc silicate, and more than half as active photographically as plain calcium tungstate.

(*b*) *Form of screen.*

Braun's screen, the purpose of which was to carry the fluorescent layer, was a flat circular disc of mica. Mica was used because it is light and rigid, is easily mounted in position, will withstand the heat of the glassworking in constructing the instrument, and has no adverse effect on the vacuum conditions. Later glass was used in place of mica, by Varley (1902, loc. cit.); it has the advantage of greater transparency, allowing the cyclogram figure to be viewed from either side of the screen. The importance of this for recording by photography was pointed out by Rankin.‡‡

The theory of the deflection of the electron jet (see Appendix) shows that when the deflecting field is finite in extent so that the jet travels across a free space before reaching the screen, then the correct shape for the screen surface is a plane, oriented in such a way that the undeflected or zero position of the jet is a normal to the plane. Further, if deflection is obtained by immersion of the whole jet instrument in the field, this rule still holds when the field is electrostatic; but when it is magnetic [see Thomson * (1897), Knipp and Welo † (1915), and others] it is no longer mathematically accurate. However, in all the jet instruments so far described the maximum angular deviation of the jet that can be recorded is limited, and the error introduced by the use of a flat screen in such a case is well within the limit of accuracy of the instrument.

It has been found convenient to dispense with a separate screen, the fluorescent layer being mounted directly on the inner surface of the vacuum vessel, when this is of glass. This has the advantage of simplifying the construction of the instrument, and further, it favours photographic recording from the rear of the screen [see Section VII, A, 3, (*b*)]. Now in portable instruments, such as that designed by Johnson ‡ (1922), this surface must necessarily possess considerable curvature, and this produces a distortion of the record. Johnson expresses the error of his instrument in the following terms: If the pattern is recorded by a camera whose lens is 2 cm from the end of the tube, the apparent reduction of deflection produced by curvature of the bulb is given in terms of the deflection γ approximately by

$$\partial\gamma = \frac{20 + D}{400D}\gamma^3 \text{ cm } §$$

(2) MEASUREMENT OF DEFLECTION.

When an electron-jet instrument is used with linear deflection for measuring a steady quantity, a measure of the deflection of the indicator spot, in terms of length, is sufficient information. In Thomson's instrument the indicator line moves on the glass, and the desired result is quite simply obtained by attaching a bent scale to the glass and reading off the deflections, as in an ordinary measuring instrument with mechanical pointer and scale. On the other hand, when the indicator is a fluorescent spot on a screen, mounted inside the tube, such direct reading is not possible unless the screen itself is provided with a suitable scale.

Varley ‖ (1902) made direct measurements of deflection (linear) on the internal screen of his Braun's tube by optically projecting a scale on to the screen—the scale was cut in tin-foil on glass, strongly illuminated from behind, and the lenses were arranged to give exactly millimetre divisions on the screen. Later, however, the instruments made by Müller-Uri were provided with glass screens carrying a "graticule" of uniform millimetre squares engraved on the uncoated side.

(3) RECORDING DEVICES.

(*a*) *Manual.*

(i) *Ruled screen method.*—With two-dimensional working it is preferable to secure a separate copy or record of the oscillogram or cyclogram, upon which measurements may be made of angle, area, etc., as well as of length. The graticule or ruling on the fluorescent screen provides a ready means for making such a copy, for if a copy of the graticule is available on a sheet of paper, the figure may be drawn in, freehand, with an

* See Bibliography, (109). † *Ibid.*, (1). ‡ *Ibid.*, (110). § *Ibid.*, (84). ‖ *Ibid.*, (85). ¶ *Ibid.*, (90). ** *Ibid.*, (101). †† *Ibid.*, (99). ‡‡ *Ibid.*, (81)

* See Bibliography, (67). † *Ibid.*, (93). ‡ *Ibid.*, (101).
§ This formula refers only to the particular instrument designed by Johnson.
‖ See Bibliography, (109).

accuracy at least as good as that of the figure as it appears on the screen. If the screen is ruled with uniform squares, ordinary squared graph paper may be used for the copy; this can be obtained with different sizes of squares, and hence a magnification or a reduction in size of the figures may be made if desired. Similarly with a non-plane fluorescent layer, any approximately uniform lines may be marked upon it and the resulting graticule photographed, the copy of the figure being drawn on a photographic reproduction of the graticule.

The process is not very rapid, and necessitates the figure remaining accurately steady on the screen during the copying; on the other hand, the measurements required may often be obtained by copying portions only of the figure—thus speed and accuracy may be combined.

(ii) *Tracing desk method.*—An alternative method of making the copy, more complicated but possibly more accurate, is to trace it on a lightly-smoked glass plate, the eye being kept in a fixed position during the process. This method was the one adopted by Ryan * (1911). The record was made from the front or coated side of the fluorescent screen; but distortion due to the necessarily angular view was eliminated by placing the tracing plate parallel to the screen. This plate is mounted over an aperture in the bottom of a shallow light-tight box lined with white paper; a corresponding aperture in the top admits the tracing point, and the open end admits light from a lamp so that the tracing point and the traces made shall be visible without light being thrown on the screen of the cyclograph.

(*b*) *Photographic.*

(i) *With camera.*—Zenneck † (1899) recorded his cyclograms by photography with an ordinary camera and sensitive plate, the tube and camera being darkened to prevent reflection of extraneous light by the screen or the glass of the tube. The exposure time necessary with normal operation of the instrument was about 10 minutes. This time could be shortened by using a stronger discharge (the exciting machine being run at its maximum speed), 6 to 20 secs. being required for recording a cyclogram, and 1 to 2 secs. for the stationary spot. It has been noted, however, that satisfactory operation of the cyclograph was not obtainable with this heavy discharge.

Ångström ‡ (1900), using a tube made to Braun's specifications, adopted the same method; half-size photographs of the cyclograms were obtained with 10 to 20 seconds' exposure.

Ryan § (1903) who obtained a larger tube and ran it with a heavy discharge was able to secure satisfactory photographs with an exposure of 2 to 5 secs. Such records are faint but sufficiently visible, and are therefore the best as they give the finest trace and so make for accurate measurements. For reproduction purposes, and especially for making lantern slides, the exposure must be considerably longer to secure sufficient contrast; this results in a much broader and more indefinite trace.

* See Bibliography, (82). † *Ibid.*, (77). ‡ *Ibid.*, (111). § *Ibid.*, (79).

Rankin * (1905) points out that in the tube used by Ryan the screen was made of a thick quality of mica, and since the photographs were taken from the back of the screen the mica would account for a considerable absorption of the actinic rays.

Varley and Murdoch † (1905), using a Braun tube having a calcium tungstate screen taking $0{\cdot}02\mu A$ with 4 mm equivalent spark-gap, obtained records with exposures of 20–30 secs.

Chaffee ‡ (1911) photographed the front (fluorescent) side of the screen, obtaining natural-size records with exposures of 3–30 secs.

Zenneck § (1913), who passed 0·5mA at 28kV through his Braun-type tube, and Samson ‖ (1918), who with a hot cathode used a tube current of up to 10mA at 9kV, obtained records on moving plates, i.e. with only a single traversal of the indicator (image of fluorescent spot).

Johnson ¶ (1922), by using a hot (coated filament) cathode and a special focusing method, combined with a sensitive fluorescent layer, found 20 secs. sufficient exposure for an average repeated-trace cyclogram, in spite of the low velocity of his jet; a "modulation diagram," in which the indicator has to cover an area to indicate its envelope, required an exposure of 2 mins.

(ii) *By contact photography.*—This method is applicable only to those instruments in which the fluorescent material is on the inner surface of the glass wall of the tube. The principle is to apply the light-sensitive film in contact with the outer surface of the same glass wall; then the film is acted upon by light directly radiated from the fluorescent layer. The trace obtained on the film will naturally be considerably broader and with more indefinite edges (like a penumbra effect) than the light trace on the fluorescent layer; but in practice the loss of accuracy on the record will not be great, unless the glass is unusually thick. It may be noted that of available instruments, that developed by Johnson lends itself well to this method of recording, for its glass is thin and of uniform thickness over the fluorescent area. The loss of accuracy may in fact be partially compensated by the shorter exposure possible, on the lines of Ryan's experience [see Section VII, A, 3, (*b*), (i)], for evidently the proportion of the light emitted by the fluorescent material that acts on the sensitive film is enormously greater with the contact method than it is when a camera and lens are used.

One way applicable when the curvature to be accommodated is not too great is to use a gelatine film stretched across a light frame instead of being mounted on celluloid or glass, carrying the sensitive emulsion in the usual manner. This film will be elastic and will fit against the curved glass surface of the electron-jet instrument, giving the necessary contact. When the exposure is completed the film will regain its flat shape, so that contact prints may be made from it on ordinary flat paper. Obviously such a film requires very careful handling in all the stages from manufacture to the final print; and a further cause of unreliability is the distortion of the record due to imperfect elasticity and the wetting and drying of the gelatine. An improve-

* See Bibliography, (81). † *Ibid.*, (112). ‡ *Ibid.*, (84). § *Ibid.*, (113). ‖ *Ibid.*, (96). ¶ *Ibid.*, (101).

ment on this is to prepare a plaster cast of the curved glass surface, and mount the sensitized gelatine film on the surface of the cast—for example, it may be manufactured in situ by the wet-plate process. With this device distortion of the film is eliminated, and it is possible to establish contact over the full area, unrestricted by the curvature of the surface. To prepare a flat record it is necessary to resort to the use of a camera and photograph the negative (which is on the plaster cast); thus almost the same result is obtained as though the trace on the fluorescent layer had been photographed with a camera, but the long exposure part of the process has been eliminated.

With either of these methods it is necessary to make allowance for the distortion of the cyclogram due to the curvature of the fluorescent layer, should the amount of error be not negligible [see also Section XI, A, 1, (*b*)]. A convenient method when linear dimensions of the cyclogram are required is to make the apparatus prepare its own graticule—one component deflection is made an alternating motion, while the other is held at a number of standard values of deflection in turn; then this process is repeated with the component deflections interchanged. The flat record obtained from this is superimposed upon the cyclogram with the axes coinciding correctly, and is used as the scale from which measurements are read.

(B) With Internal Photographic Plate.

(1) General.

The methods of recording that have hitherto been described (see Section VII, A) take time to accomplish; hence they are on a par with the step-by-step methods of determining wave-form, in so far as they are applicable only to periodic phenomena which can be held sufficiently constant during the time of recording. In general such procedure is inapplicable to the recording of transient phenomena. Dufour * (1914) suggested that it would be necessary to have an arrangement of apparatus permitting direct registration of the electron jet on a photographic plate. Even with direct registration he found that for high-frequency work it was essential to use a much more intense electron jet (see Section IV) than that obtained in tubes of the kind used by Braun, Zenneck, etc., in order that a single traverse of the jet might leave a readable trace; and, further, constancy of the jet itself became an essential condition.

(2) Modifications in the construction of the instrument.

In the electron-jet instrument, as it has so far been developed, the jet operates only inside the vacuum chamber—hence if it is to impinge directly on a photographic film this film must also be mounted inside the vacuum chamber. The method of mounting the film or plate depends upon the time scale in use (see Section VIII)—thus a rotating drum may carry a film, winding spools may carry a roll-film, or a magazine may carry a film-pack or a number of plates. In each case it is usual to arrange the whole mechanism inside a light-tight box or camera, so that the instrument is made daylight loading.

* See Bibliography, (87).

The first requirement is that the vacuum chamber shall have a door which will admit this camera when open, and which can be made vacuum-tight with a minimum of trouble when closed. Secondly, if the time-scale motion is imposed on the recording surface, a suitable drive must be fitted [see Section VIII, C, 2, (v)]. Thirdly, means must be provided for changing the plates of a magazine, or for winding a roll-film, and for opening and closing the shutter of the camera. This shutter is of the same size as the recording area and, when closed, lies parallel to it; it frequently carries a fluorescent coating, so that the instrument may be operated visually when required. The details of construction and the technique of operation of this accessory apparatus have been developed largely by Knipp and Welo * (1915), Dufour † (1920), Keys ‡ (1921), and Wood § (1923).

In addition to these modifications in the construction of the instrument, it is necessary to have it permanently connected to an exhausting plant, since the vacuum is lost each time the instrument is opened. As a result it is no longer possible to make the instrument portable, and the total cost of the plant is considerably increased. In the matter of convenience in use, with modern exhausting equipment it is possible to evacuate the instrument ready for use in a comparatively short time—Dufour on his oscillograph (using a mercury-vapour diffusion pump) obtains sufficiently rapid working to enable 4 to 6 films (from the rotating drum) or 20 to 30 plates to be exposed in an afternoon.

(3) Sensitivity of the photographic plate to cathode rays.

The problem of recording on a photographic plate by direct activation by the cathode rays may in a sense be regarded as opposite in nature to that of recording the impact of X-rays. A normal photographic plate, working with light rays, absorbs a high proportion of the energy of the light falling upon it, and a good proportion of this absorbed energy is useful in activating the silver salt in the emulsion. Now the tendency with X-ray work, and especially with "hard" rays, is for the rays to penetrate through the plate, so that only a small proportion of the incident energy is absorbed by the sensitive emulsion. To absorb a higher proportion of the incident energy, and secondly to transform this as much as possible into a form that will activate the emulsion, different devices have been adopted, such as thicker and double emulsions; loading with lead and thorium salts, whose "soft" characteristic radiations are excited and add their blackening effect; and coating with fluorescent material (sometimes on a separate carrier, making an "intensifying screen," placed behind the plate), which adds its light radiation.

With cathode rays, on the other hand, the rays are too readily absorbed by the plate. In an average cold-cathode tube the penetration of the rays into the gelatine film is of the order of 0·02 mm, so that only

* See Bibliography, (93 and 94). † *Ibid.*, (88 and 89). ‡ *Ibid.*, (97). § *Ibid.* (99).

a small proportion of the silver can be affected by the rays. Further, the incident energy is expended only partly on silver granules, which is where it is wanted; the remainder is absorbed by the gelatine. Thus Dufour finds that there is little advantage in sensitivity to be obtained by using fast plates rather than slow ones, whereas they have the distinct disadvantage of being more liable to "fogging" by stray radiation. Wood * (1923) confirms this (ordinary plates of about 150 H. and D. were usually employed), and finds further that "Schumann" plates give greatly superior results—a visible photographic impression is obtained with a "velocity of traversal" of the jet across the plate reaching 1 000 m/sec., whereas with ordinary plates the records appear rather faint when the velocity of traversal exceeds 50 m/sec. (the accelerating P.D. producing the jet was 3 kV). The Schumann plates were developed originally for work with ultra-violet radiation, for which the absorption problem tends in the same direction as that for cathode rays: they are made with a minimum quantity of gelatine, so that all the active silver shall be contained in a very thin surface layer, and hence lie within reach of the quickly absorbed incident radiation. The use of the Schumann type of plate is all the more desirable with the low-velocity jets of hot-cathode instruments, on account of their smaller penetrating power.

An additional method of obtaining increased sensitivity of a photographic plate to cathode rays is to use fluorescent material (as has been done for "hard" X-rays, see above).

Levy, West, and Baker † used calcium tungstate dusted over an ordinary photographic plate, and exposure was made in the usual manner. Wood had plates made with calcium tungstate mixed in with the sensitive emulsion. The improvement in sensitivity over an ordinary untreated plate approaches the same order as that obtained with the Schumann plate.

It may be remarked here that from the use of a fluorescent layer next to the sensitized film on the plate it is only one stage to arrive at the method of Section VII, A, 3, (*b*), (*ii*), where the light radiation from the fluorescent material has to travel through the glass wall of the vacuum chamber before acting on the sensitive film.

Experiments have also been made, with some degree of success, to render plates insensitive to light whilst retaining maximum sensitivity to cathode rays. With such plates all operations, including development, can be carried out in subdued white light.

(VIII) TIME SCALES FOR OSCILLOGRAPHIC WORK.

(A) Cyclographic Method.

With the exception of the electron-jet oscillographs of Dufour, Keys and Wood, which use internal photographic plates for recording, the indications given by the electron-jet instruments that have been described are not powerful enough to imprint a satisfactory trace on any recording device with only a single transit of the indicator. From this arises the necessity of using repetition devices for the time scales, i.e. the indicator must be caused to repeat its trace on the recording plate, if possible with close accuracy, for as long a time (as many cycles) as may be necessary, just as with the cyclograph operated by two periodic quantities of integral frequency ratio (see Section I).

The simplest method is to use the instrument as a cyclograph, arranging, however, that the time-variation of the second deflecting field acting on the jet is known, or may be independently determined. This was the method adopted by Ryan * (1903), who used a pure simple harmonic motion for his time scale. The second deflecting field was produced by a solenoid, and this was fed from the a.c. mains supplying the test apparatus, through a filter consisting of a large inductance in series with a parallel oscillatory circuit which was tuned to resonate with the fundamental of the a.c. supply. With this filter it was claimed that the reduction factor on each harmonic with respect to the fundamental was $5n^3$, n being the order of the harmonic, and 5 the amplification factor of the fundamental due to resonance. The magnetic deflection produced was thus sufficiently nearly a pure sine wave.

The cyclographic method, using a simple harmonic time-scale motion, was the one adopted by Keys † (1921), Hull ‡ (1921), and Watson Watt § (1923). The last two derived the sine-wave oscillation from triode oscillators giving variable frequency. Watson Watt, using an instrument of the type developed by Johnson (see Section V, C) found it practicable to record single-trace diagrams with velocities of traversal of the indicator reaching 0·1 km/sec. (= 225 miles per hour).

(B) "Uniform" Periodic Time Scales.

(1) general.

In studying wave-forms from rectangular oscillograms it is an obvious advantage for the instrument to use a time-scale deflection which is uniform (i.e. has a linear law of variation with time), instead of a harmonic deflection such as that described above. Such a time-scale deflection may still be periodic, for though its linear law must hold for a complete cycle of the unknown periodic quantity it may thereafter become discontinuous and repeat from the starting point after any integral number of cycles of the periodic quantity.

(2) moving screen.

(*a*) *Linear.*

As has been noted in Section I, B, 2, (*a*), the time-scale motion is frequently more conveniently imposed on the recording screen instead of on the indicator; this method is in fact the more used with mechanical oscillographs.

Provided that a circular motion is used, the method lends itself well to periodic work, since the motion may be directly synchronized with the periodic quantity. Thus for an electron-jet oscillograph the sensitive film on which the record is made is wrapped around a drum, which is rotated in synchronism as above stated.

* See Bibliography, (99). † *Ibid.*, (114).

* See Bibliography, (79). † *Ibid.*, (97). ‡ *Ibid.*, (90). || *Ibid.*, (116).

The axis of the drum is set parallel to the direction of the deflection of the indicator due to the electrical quantity investigated, so that the rotation of the drum supplies the required relative motion, linear and perpendicular to the first component.

(*b*) *Circular.*

An even more convenient variation of this method is to use a flat sensitive film or plate, rotated about an axis perpendicular to its plane; the plate replaces, or is arranged parallel with, the fluorescent screen of the electron-jet instrument, as with the previous arrangements. The rotation must be synchronized just as with the rotating drum. The relative motion between plate and indicator is in this case circular, and this method is the one most used for obtaining circular and polar oscillograms. Its application to a mechanical oscillograph has been carried out by Chubb * (1914) and to an electron-jet oscillograph by Grix † (1921).

Any of the photographic methods of recording described in Section VII may be used in conjunction with the moving-plate method, equally with the fixed-plate methods, provided only that provision can be made for moving the recording surface in the manner specified above. For example, the use of internal photography on a rotating drum, working inside the vacuum chamber, has been developed by Dufour (see Section VIII, C, 2).

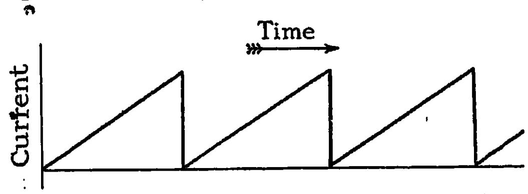

FIG. 45.—Oscillogram of Zenneck's time motion.

(3) MOVING JET.

(*a*) *Linear.*

(i) *Mechanical.*—After Braun (1897) had produced the first two-dimensional electron-jet instrument, and used it cyclographically, Zenneck ‡ (1899) proceeded to work it oscillographically. For this he imposed on the jet itself a time-scale motion that was uniform and periodic, the other component deflection being under the control of the unknown quantity; thus with proper synchronization of the time-scale deflection the recording screen showed a stationary oscillogram to rectangular co-ordinates (see Fig. 45).

To obtain this time-scale motion the jet was deflected magnetically by a solenoid coil. A revolving insulating disc, carrying a potentiometer slide wire on its edge, controlled the current in the coil, this being connected between a brush rubbing on the wire and one of the two brushes leading current to the wire (through slip-rings to which its ends were connected).

(ii) *Electrical.*—A purely electrical method of producing a uniform, periodic motion of the jet was devised by Rogowski § (1920). The electrostatic deflection of the jet was controlled by the P.D. across a condenser, and this P.D. was given a triangular wave-form (see Fig. 46) by making the current flowing through the condenser of rectangular wave-form. That is, the condenser was charged with a constant current and discharged with a constant current, this result being secured by two opposed diodes working on their saturation current; the combination is supplied with an auxiliary alternating supply whose P.D. must be large compared with that required to produce saturation in the diodes. The practical difficulties of realizing this condition of rectangular current wave-form were investigated by Rogowski and Glage.* Radio receiving valves were found to produce better results than transmitting valves, due to their saturation current being reached with a lower P.D. between anode and filament. Note from Fig. 46, for which the two diodes are assumed to work with equal saturation currents, that the return motion of the indicator is made with the same velocity as the forward motion, thus producing a second curve the opposite way round to the first. This can be eliminated by means of an interrupter, synchronized with the auxiliary supply, causing the indicator to trace out the zero time or axis on its return journey.

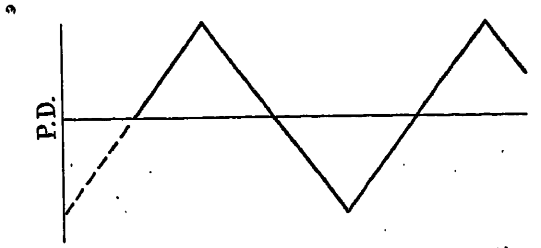

FIG. 46.—Oscillogram of Rogowski's time motion.

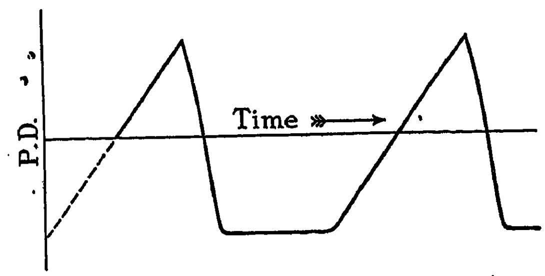

FIG. 47.—Oscillogram of Rogowski's time motion with unequal charge and discharge rates of the condenser.

Rogowski overcame the difficulty in a simpler manner, by using unequal heating of the two diode filaments. Thus the discharge of the condenser could be accomplished with a higher current, and therefore in a shorter time, than the charge (or vice versa), producing a saw-tooth wave-form of the type shown in Fig. 47. An alternative method tried by him was to allow the condenser to discharge through a spark-gap instead of through the second diode, producing a time-scale wave-form as shown in Fig. 48. This arrangement simplifies the apparatus required, but

* See Bibliography, (6). † *Ibid.*, (9). ‡ *Ibid.*, (77). § *Ibid.*, (117).

* See Bibliography, (118).

there may be complications due to high-frequency oscillations accompanying the discharge of the condenser.

If n is the number of cycles of the unknown quantity it is desired to show on the oscillogram, then each slope of the triangular wave-form must last for a time nT, where T is the time period of the unknown quantity; the time period of the auxiliary alternating supply must therefore be $2nT$, i.e. its frequency must be $1/(2n)$ of that of the unknown quantity, with the methods of Figs. 46, 47 and 48.

Another electrical method recently applied, described by Kipping * (1924), is the use of the neon-lamp oscil-

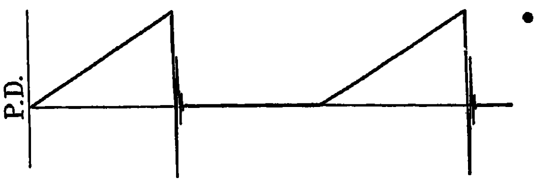

FIG. 48.—Oscillogram of Rogowski's time motion with condenser discharged by spark.

lator circuit (known also as the "flashing" or "blinking" neon lamp). In principle the method is cyclographic, for it is a P.D. oscillation derived from a potentiometer resistance in the neon-lamp circuit which produces the required time-scale motion of the electron jet. During the greater part of the time period (while the lamp is out) the current flowing into the condenser decreases according to an exponential law, but with suitable choice of the constants of the circuit and the characteristics of the neon lamp it may

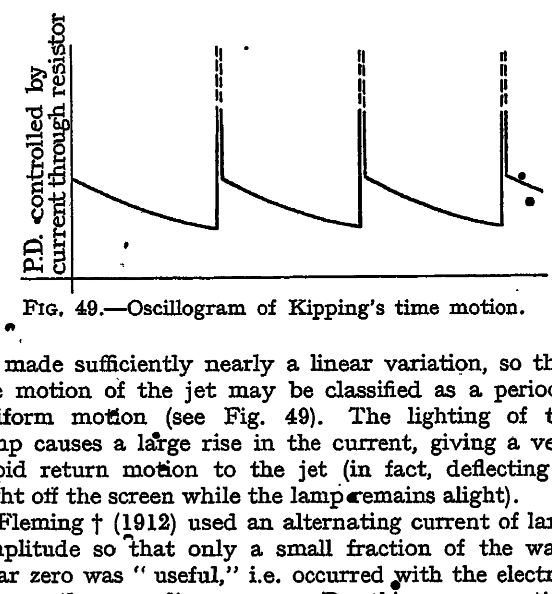

FIG. 49.—Oscillogram of Kipping's time motion.

be made sufficiently nearly a linear variation, so that the motion of the jet may be classified as a periodic uniform motion (see Fig. 49). The lighting of the lamp causes a large rise in the current, giving a very rapid return motion to the jet (in fact, deflecting it right off the screen while the lamp remains alight).

Fleming † (1912) used an alternating current of large amplitude so that only a small fraction of the wave near zero was "useful," i.e. occurred with the electron jet on the recording screen. By this means a time scale was obtained which was sensibly uniform. A method of this nature is more suited for use on transient quantities (it was in fact devised for that purpose), though this does not preclude its use for periodic quantities. To ensure that the phenomenon to be investigated would occur during the middle useful portion of the time-scale oscillation, and only once per cycle, it was controlled by a mechanically-driven commutator synchronized with the a.c. supply.

* See Bibliography, (119). † *Ibid.*, (120)

Dye * (1925) has applied this last method to periodic quantities, using the repetitions of the time scale and eliminating the mechanical interruptor. The first requirement was to separate the forward and return traversals of the jet across the screen by applying a second alternating deflecting force to the jet of the same frequency as, but out of phase with, the first one mentioned (giving the large amplitude deflection). This force was also much smaller in magnitude, so that the time-scale motion of the jet was a long, narrow ellipse, of which only the middle portion of one of the long sides was utilized. Secondly, it was necessary to secure the usual steady integral relationship (the ratio may be as high as 25) between the frequencies of the time-scale motion and the unknown quantity.

(b) *Circular.*

(i) *Mechanical.*—The time-scale component of the jet's motion may also be made circular for the production of both circular and polar oscillograms. The most direct means of doing this is to impose the circular motion on the deflecting field acting on the jet (producing in fact a rotating field). The "line of deflection" of the indicator thus becomes a "radius vector," rotating around the zero position as centre with a uniform angular velocity.

A method † for applying the circular motion in the case of an electron-jet oscillograph is as follows: The solenoid coils or condenser plates (producing a magnetic or an electric deflecting field) are mounted on hollow bearings, permitting them to be rotated about an axis coinciding with the undeflected position of the electron jet. The drive may be through chain or toothed gearing, or by a specially constructed motor whose rotor is part of the rotating deflecting apparatus; use of a synchronous motor enables the necessary integral speed relation to be obtained automatically.

It is necessary for the electron-jet instrument itself to be so designed that it can be used with this apparatus, as the jet-producing portion of it must pass at least part of the way along inside the hollow shaft of the apparatus. Further, owing to the mechanical rotation of the apparatus surrounding the vacuum tube, it is not possible to use the method for studying frequencies higher than those met with in power engineering (or in telegraphy).

(ii) *Electrical.*—As an alternative the jet may be rotated by a constant rotating electric or magnetic field. The advantage of this arrangement is the absence of both mechanical complications and inherent frequency limitation. Assuming that the resistance and the capacity may be obtained sufficiently pure, which is quite a possibility, then the arrangement in Fig. 50 (see Kipping, loc. cit.) will give the required constant rotating field (an electrostatic one) and has the merit of extreme simplicity. The necessary relation between resistance and capacity is

$$R = \frac{1}{2\pi f C}$$

* See Bibliography, (124). † *Ibid.*, (121).

where f is the frequency of the alternating supply and also the speed of rotation (in revs. per sec.) of the instrument indicator. This a.c. supply must be sinusoidal in wave-form; if necessary it may be purified by a filter such as that used by Ryan.

Note that with no unknown quantity applied to the instrument, i.e. zero indication, the indicator traces a circle; thus circular oscillograms may be obtained, but *not* polar ones. Further, both perpendicular components of deflection are occupied in producing the time-scale rotation of the indicator. The radial deflection required to give a circular oscillogram may be obtained from a deflecting device mechanically rotated in step with the indicator, but this is returning to the method just described. The radial deflection may, however, be obtained by an indirect method such as that described in the Appendix (also see Kipping, loc. cit.). In this the unknown quantity, converted to a P.D. of suitable magnitude, is added to the steady P.D. used to generate the electron jet in the instrument; this causes corresponding changes in the "sensitivity" of the jet to deflection by the constant rotating field, and the resulting changes in radius of the trace will give the required circular oscillogram when the change of velocity used is a small fraction of the constant component.

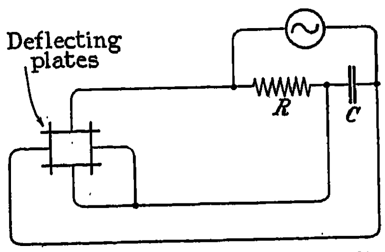

FIG. 50.—Kipping's rotator circuit.

Dye * (1925), who originated this method, used it also with a rectilinear (parallel) or a circular motion, instead of a radial one, under the control of the unknown quantity. The latter has advantages in frequency measurement work; and when the frequency ratio is high (of the order of 25, for example) the former gives an approximation to the rectangular oscillogram more simply than the radial method.

(C) "SINGLE TRACE" TIME SCALES.

(1) GENERAL.

It is obvious that the methods of recording from an electron-jet oscillograph involving the production of a stationary trace on the recording plate are inapplicable to non-periodic phenomena, and Dufour † (1914) stated that for these it was necessary to use a single-trace method, as is the common practice with mechanical oscillographs in conjunction with the "falling-plate" time scale.

After producing a form of electron-jet instrument that would give a satisfactory record under these conditions (see Section IV) Dufour devised new ways of obtaining an extended time scale (the scale factor reaching 3 km/sec., being the "velocity of traversal" of the indicator with time-scale motion only), and developed the auxiliary apparatus for applying these motions. Later * (1922) this limit was extended, the scale factor reaching 900 km/sec., enabling records to be made at frequencies up to 220×10^6 cycles per sec.

(2) MOTION IMPOSED ON SCREEN.

(i) *Sliding plate.*—Zenneck† (1913) applied the moving-plate principle to a Müller-Uri instrument—this was worked with a relatively high P.D. (28 kV) and very good oscillograms are shown in his paper. The photographic plate was carried in a dark slide which was traversed horizontally across the back of the camera by a wire wound up by a drum; the drum was driven through self-disengaging gears by an electric motor. By this means the drum, once started, made one revolution and then stopped. The drum shaft also carried a commutator which served to set in action the transient phenomenon to be investigated. The speed of the photographic plate was 1 m/sec., giving a wave-length on the record of 2 cm for a periodic quantity of frequency 50 cycles per sec.

(ii) *Rotating drum.*—Dufour ‡ (1920 and 1922) used a rotating drum for his time scale, obtaining thereby a higher velocity of the recording surface (4 to 5 m/sec.). The drum has a photographic film clipped on to its cylindrical surface which is 15 cm wide and 48·5 cm circumference. The electron jet strikes this surface normally and is acted upon by the single unknown

FIG. 51.—Dufour's time motion for low frequencies.

quantity so that it is deflected in the plane of the drum's axis. Thus a phenomenon lasting 0·001 sec. extends for 4 or 5 mm on the record; and the maximum frequency recordable is 8 to 10 kilocycles per sec. (see Fig. 51).

(iii) *Spiral trace.*—A useful modification of the method consists in superimposing on the jet a gradual traversal parallel to the drum axis (i.e. in the same direction as the unknown quantity), obtained by a magnetic field controlled through a variable resistance. This gives on the cylinder a spiral trace of considerable length and greatly facilitates the recording of transient quantities.

(iv) *Timing switch.*—On the whole, however, the better technique was found to be not to use the spiral-trace method. It became necessary then to arrange that recording should take place during only one revolution of the drum, and a "timing switch" was devised to secure this result. The shaft from which the drum is driven carries a cam and a lever which, when released by a trigger (worked by the operator), engages its pin with the cam and is carried through a cycle of operations by one revolution of the cam. This cycle commences with the switching on of power to the discharge tube generating the electron jet. Next, by means of

* See Bibliography, (124). † *Ibid.*, (87).

* See Bibliography, (89). † *Ibid.*, (113). ‡ *Ibid.*, (88 and 89)

insulated segments on the lever, on which bear brushes whose position is adjustable, the phenomena to be investigated are caused to act on the jet. The cycle closes with the switching off of the discharge tube. Thus a complete record of the phenomena may be obtained, it being possible to use the whole width of the film (length of the drum) for the amplitude of the oscillation.

The above method is described as the "first technique with the timing switch" and serves for recording wave-forms of phenomena of "low frequency" (from zero to a few kilocycles per second). Note that the drum with its film is inside the vacuum chamber, so that the electron jet impinges directly on the film surface, and the drive is by means of a magnetic clutch acting through a glass cap sealed on to the metal vacuum chamber.

(v) *Drive.*—It is not practicable to use a direct mechanical drive through a gland, because vacuum tightness must be ensured with an electron-jet instrument, and relatively high speeds of rotation are required (Dufour uses up to 600 r.p.m.). A more reliable form of drive (with which, however, the precaution mentioned below would be more necessary) is the induction-motor method; this might well be constructed on the lines of the drive to the Holweck * molecular vacuum pump. In this connection Wood † (1923) recommends

FIG. 52.—Dufour's time motion for middle frequencies.

that the magnetic or electric drive to the drum should be switched off during the actual period of recording to avoid disturbances of the jet by stray fields—the drum continues rotating by its own inertia.

(vi) *Time-scale calibration.*—Dufour uses an independent method of fixing the time scale for each record. A beam of light is periodically interrupted by an electrically driven tuning fork, and is allowed to shine on the edge of the rotating film during the period of registration (controlled in fact by the timing switch mentioned). With this arrangement no difficulty arises due to speed variation from allowing the drum to run free during the record.

(3) MOTION IMPOSED ON BOTH SCREEN AND JET.

For frequencies above a few kilocycles per second the speed of the sensitive film (on the drum surface) cannot be made sufficiently great.

The component deflection of the jet controlled by the phenomenon to be studied (called "Z") is now turned through a right angle, so that the corresponding deflection occurs perpendicular to the axis of the drum (see Fig. 52). Its place is taken by an auxiliary oscillation of the indicator (called "Y") produced by a magnetic field. This auxiliary deflection is controllable in frequency from 100 to 10 000 cycles per sec., and is given a large amplitude so that the indicator travels from end to end of the drum. In practice the power for Y is derived from a variable-speed alternator (up to 800 cycles per sec.) or from a Duddell singing arc (up to 20 000 cycles per sec. if desired). The best ratio between the frequencies of Z and Y lies between 50 and 150.

* See Bibliography, (122 and 128). † *Ibid.*, (99).

Dufour describes this method of his as the "second technique with the timing switch," and uses it for "middle frequencies" up to about a million cycles per second. It is found that the speed of rotation of the drum is still a limiting factor—a point was reached in one example shown where the auxiliary oscillation Y caused complete darkening of the film. In this example the frequency of Y was 9 000 cycles per sec., and that of the unknown Z was $1 \cdot 1 \times 10^6$ cycles per sec. Under such circumstances obviously only damped wave-trains may be investigated.

Sustained oscillations ("C.W.") may be studied if broken up into trains ("tonic train"), but the duration of each train must be less than half of the time period of Y, and the interval between trains (corresponding to "spark frequency") a considerable multiple of this period. This method was tested with Z at 150 kilocycles per sec. from an arc (Y at 2 500 cycles per sec.), using a specially-designed mercury jet interrupter giving a train frequency of 84 cycles per sec. (running at 2 520 r.p.m.).

(4) MOTION IMPOSED ON JET ONLY.

For high frequencies, of about a million cycles per second and upwards, Dufour * (1920) obtains his extended time scale wholly by auxiliary deflecting fields—the photographic plate is held stationary. The deflection Z and Y remain as before, but the relative motion of the indicator, previously produced by rotation of the drum, is now produced by a single rapid traversal of the electron jet, called "X." The method used for containing this rapid linear motion of the indicator is as follows:—The jet is first deflected well off the screen in the direction of the required traversal (to position T″, Fig. 53) with either a permanent magnet or an electromagnet. Then an air-core solenoid is excited, which gives an opposing field of twice the value; this brings the indicator to position T′. For obtaining a record, the solenoid circuit is broken, so that the indicator moves from T′ to T″.

The switch used to interrupt this circuit was a fine wire dipping into mercury and covered with alcohol; a condenser (capacity $4\mu F$) was connected across its terminals, and this with the absence of iron caused exceedingly rapid rupture of the current, so that the duration of the trace (passage of indicator across screen) could be reduced to $0 \cdot 00005$ sec.

As with the previous methods, a timing device is necessary to operate the unknown quantity and to control the high-tension power to the electron-jet instrument. For high-frequency work the latter was supplied by a step-up transformer from an alternating supply; therefore a synchronous motor was used to drive the timing device so that the instrument could be operated on the peak of the P.D. wave without necessitating the use of a rectifier or smoothing apparatus.

* See Bibliography, (88).

The method has been used for frequencies up to 70×10^6 cycles per sec; the auxiliary oscillation Y has to be of higher frequency than previously, e.g. 270 kilocycles per sec., and is supplied by a Poulsen type high-frequency arc.

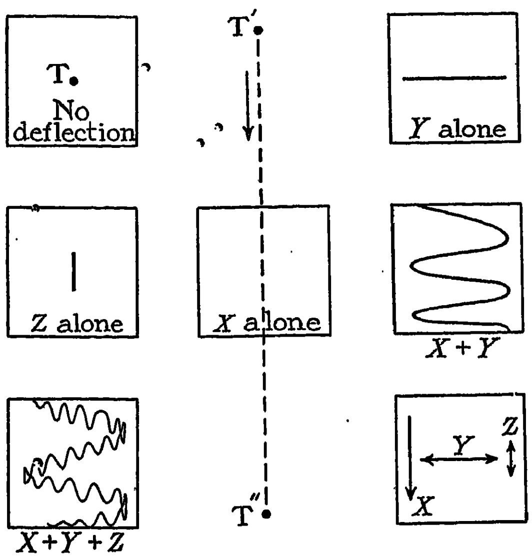

FIG. 53.—Dufour's time motion for high frequencies.

To extend the frequency range, a further stage of extension of the time-scale was tried (see Fig. 54). The deflection of the indicator caused by the phenomenon to be studied was turned through a right angle, so that it acted parallel to the auxiliary oscillation Y. Its place was taken by a second auxiliary oscillation

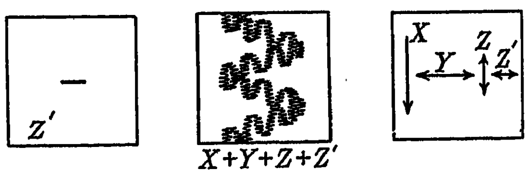

FIG. 54.—Dufour's time motion for extra-high frequencies.

(called "Z," the unknown quantity being now called "Z′") of higher frequency than Y. The power for producing Z was supplied by a Poulsen arc, up to 2×10^6 cycles per sec., for example; above this figure a spark generator was used. The method was tested with frequencies of Z′ up to 220×10^6 cycles per sec.

PART 3.

(IX) LIMITATIONS AND DIRECTIONS FOR IMPROVEMENT.

Competition with the classical types of electrical measuring instrument calls for considerably improved *deflectional sensitivity* in the electron-jet instrument, and it is to meet this demand that attention has been paid to low-velocity jets. Accompanying the use of these, however, there are two serious disadvantages, first the decrease in the *recording ability* of the jet due to its smaller power; secondly, the increased "scattering" tendency of the jet, and this not only destroys the accuracy of measurement but also detracts further from the recording ability.

The requirement here is obviously a method of focusing the jet. The problem has been solved very neatly in the oscillograph now manufactured by the Western Electric Co. In this instrument the accelerating P.D. may be as low as 250 volts, and while considerable further improvement may be still desirable this constitutes a big step in advance. Moreover, the focusing method employed in this case possesses the additional advantage of requiring an increased intensity in the jet, and this factor largely compensates for the low velocity in respect to recording ability. There seems to be no reason to suppose that the method may not be applicable to jets of even greater sensitivity.

It should be borne in mind, however, that the unique advantage of the electron-jet instrument is its faithful interpretation of electrical phenomena no matter what the frequency of variation or the steepness of wave-front; and if this characteristic is to be retained along with the improvements in other directions, alternative methods of focusing the jet must be devised. Further, unless the focusing method of itself gives sufficient improvement, it will be necessary to devise independent means for increasing the recording sensitivity of the instrument. One method that presents itself is to increase the power in the jet available at the recording screen without, if possible, affecting its sensitivity to deflection. Alternatively, the attack may be made on the fluorescent layer or the photographic emulsion to render them more sensitive to the impact of slow electrons, for example by converting a higher proportion of the incident energy into light energy. Thirdly, due to the non-proportionality between the intensity of the indication (e.g. light) and the incident energy, an improved sensitivity should be obtainable by concentrating the given total incident energy so as to give a higher energy density.

(X) CONCLUSION.

It will be seen from this survey of the subject that during the last quarter of a century there has been a vast development in the cold-cathode and later in the hot-cathode tubes, and in the technique of their application to measuring extraordinarily rapidly varying electrical quantities. Thus to-day a single transient quantity operating the tube may be seen by the eye with the spot on the fluorescent screen travelling at 225 m.p.h.; and further, with internal photography such a quantity may be recorded when the spot travels at 2 000 000 m.p.h. (i.e. 0·3 per cent of the velocity of light).

At the same time it will be obvious that finality has not been reached in this subject "Measurements in Electrical Engineering by means of Cathode Rays"; but it is hoped that future investigators may find this paper of assistance in indicating successful lines of attack.

APPENDIX.

By R. MINES, B.Sc., Student.

(XI) THE JET AS A MEASURING DEVICE.

(A) GENERAL PROPERTIES OF AN ELECTRIFIED JET.

(1) DEFLECTION OF THE JET.

(*a*) *Controlled by a deflecting field, with constant jet velocity.*

(i) *Infinite deflecting field.*—In Fig. 55 let AO represent the jet of a jet measuring instrument—it may consist of solid material particles, liquid, gas, or "non-material" particles—and let v be its constant linear velocity of projection in the direction AO. At the point O the jet emerges into the influence of a field of force, used for deflection of the jet. For the moment this field will be assumed of uniform strength and constant direction in the space to the right of O. Let the transverse component of the force acting on the jet be σ units per unit of length of the jet. Then each element of length ∂x of the jet experiences a transverse force $\sigma\partial x$. Such element, however, has a mass $\rho\partial x$. It therefore suffers a transverse linear acceleration

$$f_t = \sigma\partial x \div \rho\partial x = \sigma/\rho$$

Suppose the deflection of the jet to be observed at a point P of its path, such that it has travelled a

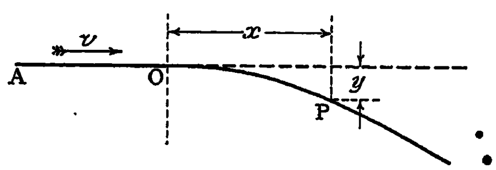

FIG. 55.—Jet entering a deflecting field.

longitudinal distance x under the influence of the deflecting field. The time taken for the element to reach P from O is x/v, and the transverse displacement that takes place during this time interval is

$$y = \frac{1}{2}\text{ (acceleration) (time)}^2 = \frac{1}{2}\cdot\frac{\sigma}{\rho}\left(\frac{x}{v}\right)^2$$

The deflection then shows a linear relation with the deflecting force. Note also that the deflection varies with the square of the distance x, and also inversely as the square of the jet velocity v.

(ii) *Finite deflecting field.*—Considering now Fig. 56, the deflecting field is shown as of finite extent, measured by L, and the jet now leaves its influence at the point Q.

From the preceding result the transverse displacement of the jet at the point Q is

$$y = \frac{1}{2}\cdot\frac{\sigma}{\rho}\left(\frac{L}{v}\right)^2$$

It may be shown also that on reaching Q the jet has a transverse component of velocity given by

$$\frac{\sigma}{\rho}\cdot\frac{L}{v}.$$

Therefore if the jet is allowed to travel a further longitudinal distance B, free from deflecting force, before observation, it will acquire an additional transverse displacement

$$y' = \frac{\sigma}{\rho}\cdot\frac{L}{v}\times\frac{B}{v} = \frac{\sigma LB}{\rho v^2}$$

The total transverse displacement at the point S is then the sum of y and y', or

$$Y = \frac{1}{2}\cdot\frac{\sigma}{\rho}\left(\frac{L}{v}\right)^2 + \frac{\sigma LB}{\sigma v^2}$$
$$= \frac{\sigma}{\rho}\cdot\frac{L}{v^2}\left(\frac{L}{2}+B\right) = \frac{\sigma}{\rho}\cdot\frac{LD}{v^2}$$

where D is the distance from the mid-point of the deflecting field to the screen (see Fig. 56).

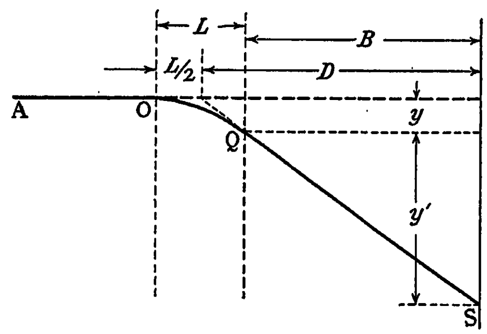

FIG. 56.—Jet passing through a bounded deflecting field.

As before, the deflection is proportional to the deflecting field when the jet velocity is held constant.

(*b*) *Controlled by the jet velocity, with a constant deflecting field.*

It will be noted in the results formulated above that the velocity of the jet is one of the factors controlling the magnitude of the deflection. Owing, however, to the inverse relationship, to preserve a definite deflection it is necessary to maintain a finite velocity of the jet. This condition is secured if the variable quantity is allowed to effect only a change in the velocity, and hence the kinetic energy of the jet (see Section XI, A, 3). The variable then may control a flow of energy (an amount of power) which is added to the normal constant power supplied to the jet.

Thus, if u is the change in the velocity of the jet, we have

$$\text{deflection } Y = \frac{1}{(v+u)^2}\cdot\frac{\sigma}{\rho}LD$$

where u is the applied variable. Similarly the resulting variable, or indicated quantity, is the change in deflection that results, i.e.

$$\begin{aligned}\partial Y &= Y_v - Y_{v+u} \\ &= \frac{1}{v^2}\cdot\frac{\sigma}{\rho}LD - \frac{1}{(v+u)^2}\cdot\frac{\sigma}{\rho}LD \\ &\doteq \frac{\sigma}{\rho}LD\frac{2vu+u^2}{v^2(v+u)^2}\end{aligned}$$

This complicated expression simplifies considerably in the case when u is sufficiently small to be negligible in comparison with v, for then v may be written for $(v+u)$, and u^2 may be neglected, so that

$$\partial Y = 2\frac{\sigma}{\rho}LD\frac{u}{v^3}$$

i.e. it is proportional to the applied variable u, and is also inversely proportional to the cube of the constant component of the jet velocity.

(2) FREQUENCY ERROR.

(*a*) *Deflectional error.*

Referring again to Fig. 56, it will be seen that each element ∂x of the jet is in its turn under the influence of the deflecting field for a finite time interval, the time L/v which the element takes to pass from O to Q. It may be verified from the investigation below that the deflection registered by the jet measures not any instantaneous value of the quantity controlling the deflection (as has been assumed in Section II) but its average value (arithmetic mean, because of the linear law) over the interval of time L/v. But obviously, as long as the fractional variation of the quantity during this time interval is negligible, the deflection may be regarded as measuring the instantaneous value, corresponding for example to the instant when the jet element passes the mid-point of the field. However, this fractional variation may become appreciable, due to the rapidity of variation of the deflecting field as compared with the jet velocity, i.e. the mean value registered by the jet ceases to be equal to the instantaneous value required; the difference is the *frequency error* of the jet.

If the jet element whose deflection is considered passes point O at time t_0, then the deflection is equal to

$$\left\{K\int_{t_0}^{t_0+(L/v)} f(t)\,\partial t\right\} \div \frac{L}{v}\,*$$

the deflecting field being a function of time [i.e. $\sigma = f(t)$], and this is not necessarily equal to the instantaneous value

$$Kf\left(t_0 + \frac{1}{2}\cdot\frac{L}{v}\right)$$

In the first instance assume the case of a sinusoidal periodic quantity, such that

$$\sigma = X\sin(2\pi ft)$$

where f is its frequency.

* Here K is the "calibration constant" of the jet instrument, and from Section XI, A, 1, (*a*) (ii) $K = LD/(\rho v^2)$.

For convenience call $\quad 2\pi ft_0 = \theta$

and
$$2\pi f\frac{1}{2}\cdot\frac{L}{v} = \phi$$

Then the required instantaneous value

$$\begin{aligned}&= X\sin 2\pi f\left(t_0 + \frac{1}{2}\cdot\frac{L}{v}\right) \\ &= X\sin(\theta+\phi)\end{aligned}$$

But the indicated deflection, divided by K, gives

$$\begin{aligned}&\left\{\int_{t_0}^{t_0+(L/v)} X\sin 2\pi ft\,\partial t\right\} \div \frac{L}{v} \\ &= \frac{v}{L}X\frac{1}{2\pi f}\Big[-\cos 2\pi ft\Big]_{t_0}^{t_0+(L/v)} \\ &= \frac{vX}{2\pi fL}\left[-\cos 2\pi f\left(t_0+\frac{L}{v}\right) + \cos(2\pi ft_0)\right] \\ &= \frac{X}{2\phi}\left[-\cos(\theta+2\phi)+\cos\theta\right]\end{aligned}$$

which reduces to

$$\frac{X}{\phi}\sin\phi\sin(\theta+\phi)$$

Thus the ratio of the measured quantity to the true value constitutes a correction factor by use of which allowance may be made for the frequency error.

$$\begin{aligned}\text{This ratio } R &= \frac{\text{indicated value}}{\text{required instantaneous value}} \\ &= \frac{(X/\phi)\sin\phi\sin(\theta+\phi)}{X\sin(\theta+\phi)} \\ &= \frac{\sin\phi}{\phi} \quad\text{or}\quad \frac{v}{\pi fL}\sin\left(\frac{\pi fL}{v}\right)\end{aligned}$$

This relation between R and ϕ is shown in Fig. 57. Notice that R is a periodic function of ϕ, with an amplitude decreasing as ϕ increases, i.e. as the frequency f is progressively increased, or the jet velocity v is progressively decreased, the factor R falls from its initial maximum value unity, passes through zero to a negative maximum (value about $-0{\cdot}22$), swings back through zero to a positive maximum, and so on.

For small values of ϕ it will usually be more convenient to determine the fractional or percentage error; thus

$$\begin{aligned}\text{fractional error } \delta &= 1 - R \\ &= 1 - \frac{\sin\phi}{\phi}\end{aligned}$$

From Fig. 58 we read the following values :—

Percentage error	0·01	0·1	1·0	10
δ	$\frac{1}{10000}$	$\frac{1}{1000}$	$\frac{1}{100}$	$\frac{1}{10}$
$\phi = \frac{\pi fL}{v}$ ..	0·024	0·077	0·246	0·79
$\frac{fL}{v}$ ..	0·00765	0·0245	0·0784	0·252

It will be seen that, up to the highest value shown, the error follows closely a square law with respect to ϕ, the relation being approximately

$$\delta = 0 \cdot 165\phi^2$$

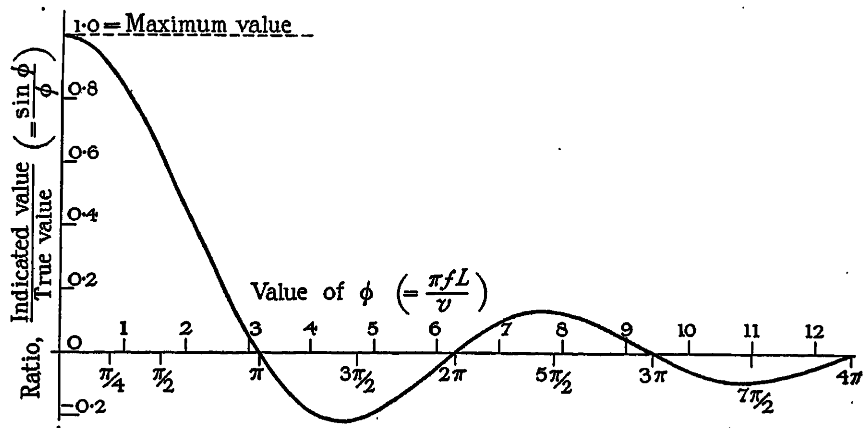

FIG. 57.—High-frequency error of the electrified jet (correction factor R).

When investigating non-periodic and transient quantities, the formulæ given may be applied individually to each sinusoidal component or harmonic present.

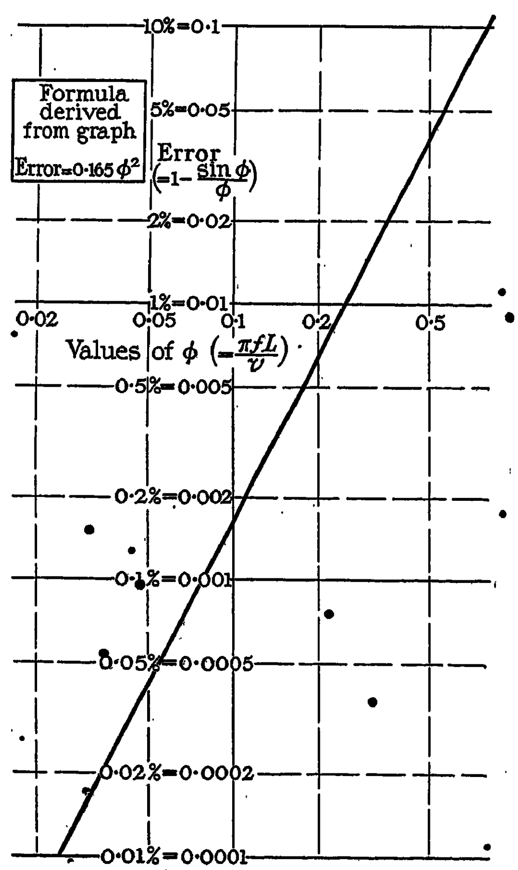

FIG. 58.—High-frequency error of the electrified jet (error δ).

(b) *Phase error.*

In jet cyclographs it commonly happens that the two deflecting fields act on the jet at different parts of its path. The difference in sensitivities, due to the different distances between the two deflecting fields and the recording screen, is easily allowed for in the calibration of the instrument, but a further error arises due to the finite velocity of the jet. If M is the effective distance between the two deflecting fields, then each element of the jet takes a time M/v to pass from one field to the other. As a result this time-lag appears as an error on the cyclogram; with periodic deflecting quantities it may be interpreted as a phase difference; and with sinusoidal quantities as a phase angle, α; then

$$\frac{M}{v} = \frac{\alpha}{2\pi}T, \quad \text{or} \quad \frac{M}{v} = \frac{\alpha}{2\pi f}$$

where T is the time period and f the frequency of the periodic quantity. Thus

$$\alpha = \frac{M}{v} \times 2\pi f$$

This error may be allowed for by taking a second cyclogram with the positions of the deflecting fields interchanged. This second cyclogram must be corrected for the differing sensitivities, so that each quantity preserves the same calibration constant for the two cyclograms. The two cyclograms are then correctly superimposed, i.e. with corresponding axes coinciding in both direction and sense; then since the error in the second cyclogram is of the same magnitude as, but opposite in sign to, that in the first, a mean curve between the two will give the correct time relation between the two periodic quantities.

(3) POWER IN THE JET.

Each element of length ∂x of the jet has a mass $\rho\partial x$ and travels with a velocity v; it therefore possesses an amount of kinetic energy $\frac{1}{2} \times \rho\partial x \times v^2$.

The time taken by such an element to pass a fixed point is $\partial x/v$. Hence the number of elements passing

such a point in unit time is $v/\partial x$ and the total energy of these is

$$\{\tfrac{1}{2} \times \rho\partial x \times v^2\} \times \frac{v}{\partial x}$$
$$= \tfrac{1}{2}\rho v^3$$

which is the power flowing past the fixed point and carried by the jet (note that it is proportional to the *cube* of the velocity).

(B) The Electron Jet.

(1) Physical constants of the electron.

The electron carries an electric charge or quantity of electricity which, having so far proved to be indivisible, may be regarded as the "atom" of electricity. Its value is

$4 \cdot 77 \times 10^{-10}$ electrostatic units
$1 \cdot 59 \times 10^{-20}$ electromagnetic units
or $1 \cdot 59 \times 10^{-19}$ coulombs

When in motion the electron behaves as though it possessed mechanical inertia, which for low velocities of motion (compared with the velocity of light) remains constant at the value

$$8 \cdot 96 \times 10^{-28} \text{ gramme}$$

It is perhaps more strictly accurate not to call this quantity "mass," but to define it as the ratio of a force which may be applied to the particle, to the linear acceleration of the particle caused by the applied force —for it is found that when the electron moves with velocities in the neighbourhood of that of light this ratio increases in value.

Lorentz, Abraham and others have suggested explanations of this phenomenon, and have deduced formulæ depicting the relation between inertia and velocity. Jones * has shown recently, however, that the formulæ of Lorentz more nearly fit his experimental results on cathode rays, and accordingly these formulæ are used here. They show that the increase of the inertia of the electron is greater for forces acting parallel with the velocity (longitudinal forces) than for forces acting perpendicular to the velocity (transverse forces), the ratios of increase being as follows :—

For longitudinal forces, $m_l/m_0 = (1-\beta^2)^{-3/2}$
and for transverse forces, $m_l/m_0 = (1-\beta^2)^{-1/2}$

where β is the ratio of the electron velocity to the velocity of light.

It will be discovered in a succeeding Section (XI, B, 3) that the determining factor in the response of an electron to a deflecting force is the ratio of its charge to its inertia; the value for low velocities is

$1 \cdot 77 \times 10^7$ C.G.S. (electromagnetic) units per gramme
or
$1 \cdot 77 \times 10^6$ coulombs/gramme.

It is this extremely high value that renders the electron so useful in jet-measuring instruments, since it enables reasonable sensitivity to deflection to be obtained in spite of the very high velocities of the electrons in cathode rays (ranging from 1/30th to 1/3rd of the velocity of light).

* See Bibliography, (125).

(2) Energy relations of the electron jet.

(*a*) *Velocity.*

An electron immersed in an electric field whose strength is X, experiences a force Xe in the direction of the field (but, with the accepted convention of signs, in the *opposite sense,* due to the charge e on the electron being negative). In the absence of constraint, therefore, the electron moves, and for each element ∂x of its path it acquires energy by an amount $Xe\partial x$; hence if it starts from rest and moves a distance x without resistance its total kinetic energy becomes

$$W = \int_0^x Xe\partial x = e\int_0^x X\partial x$$

But $\int_0^x X\partial x$ is the potential difference E over the distance x, hence

$$W_x = eE$$

Now $W_x = \tfrac{1}{2}m_l v^2$, m_l being the inertia of the electron in the direction of the acquired velocity,

whence $v^2 = Ee \div \tfrac{1}{2}m_l$

and $v = \sqrt{\left(\frac{2Ee}{m_l}\right)}$

The velocity then is proportional to the square root of the accelerating P.D., as long as the inertia remains sensibly constant. The exact relation is shown in Fig. 59.

(*b*) *Power.*

If ν is the linear density of electrons in the jet, then the rate of flow of electrons is νv. But each carries an amount of energy $W = \tfrac{1}{2}m_l v^2$, therefore the rate of flow of energy, or power carried by the jet, is the product

$$\tfrac{1}{2}m_l\nu v^3$$

As in the general case (Section XI, A, 3), this is proportional to the *cube* of the velocity.

Alternatively, however, $W = eE$, giving power in jet

$$= eE \times \nu v$$

Now $\nu v \times e$ is the rate of flow of charge, i.e. the current I carried by the jet, whence

$$\text{power} = EI$$

(3) Deflection of the electron jet.

(*a*) *Field control.*

(i) *By an electric field.*—In an electron jet which is under the influence of an electrostatic deflecting field whose component perpendicular to the jet has the value X, the transverse acceleration of the jet is that

of its component particles, and from the preceding Section this is

$$f_t = \frac{Xe}{m_t}$$

m_t being the inertia of the electron in a direction perpendicular to the jet velocity.

From Section XI, A, 1, (*a*), (ii), the deflection registered by the jet on the screen is

$$Ye = f_t\frac{LD}{v^2}$$

$$= \frac{XeLD}{m_tv^2}\left[= \frac{Xe\sqrt{\{1-(v^2/c^2)\}}}{m_0v^2}LD\right]$$

The deflection varies inversely as the *square* of the jet velocity.

(ii) *By a magnetic field.*—If the jet is immersed in a magnetic field whose component perpendicular to the jet is H, the force acting on the element ∂x is given by

$$H\partial xI = H\partial x\,.\,vev$$

But the inertia of this element of the jet to transverse forces is $\nu\partial x\,.\,m_t$, since there are $\nu\partial x$ electrons contained in the element; its transverse acceleration will therefore be

$$f_t = H\partial x\,.\,vev \div \nu\partial x\,.\,m_t$$

$$= \frac{Hev}{m_t}$$

As before, the deflection registered by the jet is

$$Y_m = f_t\frac{LD}{v^2}$$

$$= \frac{HeLD}{m_tv}\left[= \frac{He\sqrt{\{(1-(v^2/c^2)\}}}{m_0v}LD\right]$$

Note that in this case the deflection varies inversely as the *first power* of the jet velocity.

(iii) *Specific sensitivity.*—In an actual electron-jet instrument, the lengths L and D, and the value of the deflecting field for a unit applied electrical quantity, depend upon the construction of the instrument. Hence the value of the jet as a measuring device in any particular instrument is found by eliminating these factors from the measured sensitivity of the instrument—the result, which may be called the "specific sensitivity" of the jet, for deflection by an electric field is

$$Y_e \div XLD = \frac{e}{m_tv^2}$$

and similarly for a magnetic field it is

$$Y_m \div HLD = \frac{e}{m_tv}$$

In the case of an electron jet, therefore, the relation

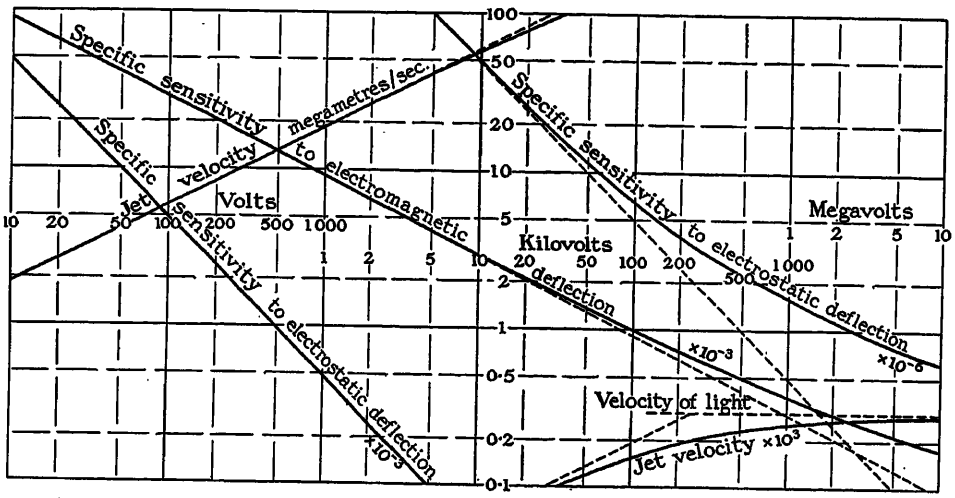

FIG. 59.—Properties of the electron jet.

between the specific sensitivity and the velocity of the jet is more complex than in the general case. Fig. 59 enables the relation to be determined.

Nevertheless, over the range for which the electron inertia (m_t) may be regarded as constant, the specific sensitivity varies inversely as the square of the jet velocity for electric deflection, and inversely as the first power for magnetic deflection. Thus a high-velocity jet is relatively more sensitive to magnetic deflection, and a low-velocity jet relatively more sensitive to electric deflection.

(*b*) *Velocity control.*

(i) *With constant electric field.*—As in the general case [see Section XI, A, 1, (*b*)] the deflection of the electron jet may be controlled by its velocity, the jet passing through a constant deflecting field, equally as well as by a variable field acting on a constant velocity jet.

If the constant field is an electrostatic one, the deflection (from the preceding Section) is

$$Y_v = \frac{XeLD}{m_tv^2}$$

and when the variable component u is added to the velocity the deflection is

$$Y_{v+u} = \frac{XeLD}{m_t(v+u)^2}$$

The useful indication of the instrument is therefore the difference, which was found to be

$$\partial Y = \frac{XeLD}{m_t} \cdot \frac{2vu + u^2}{v^2(v+u)^2}$$

In circular oscillograms, more especially with a high ratio between the frequency of the applied periodic quantity and the speed of rotation of the time scale, it is possible to work with ∂Y small compared with Y; this means that u is small compared with v, and renders possible a simplification of the above expression, which in turn simplifies the calibration of the instrument.

Then in the limit when u/v is negligible, ∂Y becomes

$$\partial Y = 2\frac{XeLD}{m_t} \cdot \frac{u}{v^3}$$

i.e. a linear law holds between the indication and the applied quantity.

It may be mentioned here that it is desirable to keep u relatively small when a high-velocity jet is used, to minimize errors due to the change of inertia (and hence in deflectional sensitivity) with change of velocity.

(ii) *With constant magnetic field.*—When the field used is a magnetic one, the expression for the deflection is

$$Y_v = \frac{HeLD}{m_t v}$$

and similarly $$Y_{v+u} = \frac{HeLD}{m_t(v+u)}$$

whence the useful indication is

$$\partial Y = \frac{HeLD}{m_t} \cdot \frac{u}{v(v+u)}$$

and when u is negligible compared with v, this reduces to

$$\partial Y = \frac{HeLD}{m_t} \cdot \frac{u}{v^2}$$

i.e. the linear law holds just as in the previous case.

(4) FREQUENCY ERROR.

(*a*) *Deflectional error.*

In Section XI, A, 2, (*a*) it has been determined that for errors up to 10 per cent at least, the frequency error δ for an electrified jet (expressed as a fraction of the true value) follows closely the relation

$$\delta = 0{\cdot}165\left(\frac{\pi f L}{v}\right)^2$$

This formula applies without modification to the electron jet, though it is more convenient to transpose it into the form

$$\left(\frac{fL}{v}\right)^2 = \delta \div 0{\cdot}165\pi^2$$

or $$f = \frac{v}{L} \times 0{\cdot}783\sqrt{\delta}$$

where f is the frequency limit for a specified error δ of an instrument wherein L and v are known.

(*b*) *Phase error.*

Similarly, from Section XI, A, 2, (*b*), the phase error

$$a = \frac{2\pi f M}{v}$$

and this formula also applies directly to the electron jet. Transposing, we have

$$f = \frac{v}{M} \cdot \frac{a}{2\pi}$$

Note that $a/(2\pi)$ is the phase error expressed as a fraction of a cycle.

(5) "SCATTERING" OF THE ELECTRON JET.

(*a*) *The dispersive force.*

It has been noted (Section VI) that one of the causes of the scattering of the electron jet is the inherent mutual repulsion between the electrons composing the jet, and it is proposed here to investigate the forces causing such motion and hence determine the relative importance of the effect.

Assume an electron jet whose initial condition is an exactly parallel motion of its electrons, their velocity being constant and equal to v cm per sec. Further assume that the jet is circular in cross-section and that initially there is uniform distribution of the electrons over the whole cross-section.

In Figs. 60 and 61 is shown a cross-section of the jet; the circle ACBD represents the boundary of the jet, of radius R cm and centre P. Let O be any electron within the jet, the force on which it is required to determine; define its position by its distance from the jet axis, x = PO.

By symmetry it will be seen that the forces exerted on the electron O by the electrons within the segment ADBO are neutralized by the forces of those in the portion AEBO; this portion is a segment of a circle also of radius R, whose centre is Q, such that PD = EQ = R.

It is necessary to consider therefore only the part of the jet AEBC; the force on the electron O due to this is radially outwards along the direction OQ. Suppose this part to be divided into a large number of elementary longitudinal filaments, each of cross-sectional area dA, where A is the cross-sectional area of the whole jet ($A = \pi R^2$).

If ν is the linear density of electrons in the whole jet, then $(\partial A/A)\nu$ is the linear density of electrons in each filament, and the linear density of charge is $(\partial A/A)\nu e$.

* Extracted from a Report to the British Electrical and Allied Industries Research Association.

It may be shown that the force exerted on electron O by the whole filament is

$$2\frac{e^2\nu}{r\kappa}\cdot\frac{\partial A}{A}$$

where r is the distance of the fialment from O, and the required radial component is

$$\frac{2e^2\nu\partial A}{r\kappa\,.\,A}\cos\theta=\frac{2e^2\nu}{\kappa A}\cos\theta\partial\theta\partial r$$

since $\partial A=\partial r\times r\partial\theta$.

The radial force due to the elementary sector KM is obtained by integrating this expression with respect to r between the limits $r_1 = \text{OK}$ and $r_2 = \text{OM}$. The result is

$$\frac{4e^2\nu x}{xA}\cos^2\theta\partial\theta$$

Similarly by integrating with respect to θ between the limits $-\frac{1}{2}\pi$ and $+\frac{1}{2}\pi$ (corresponding to the points A and B) the total radial force is obtained :—

$$\frac{4e^2\gamma x}{\kappa A}\cdot\frac{\pi}{2}=\frac{2e^2\nu}{\kappa}\cdot\frac{x}{R^2}$$

since $A=\pi R^2$.

Note that at any instant the force acting on any electron is proportional to x, its distance from the centre of the jet; electrons at the centre therefore experience no force, as would be expected from symmetry.

Secondly, if the distribution of electrons over the cross-section of the jet remains uniform while the jet is expanding, each electron must maintain its relative position in the jet, i.e. $x/R=\gamma$ is constant; hence the force on it is

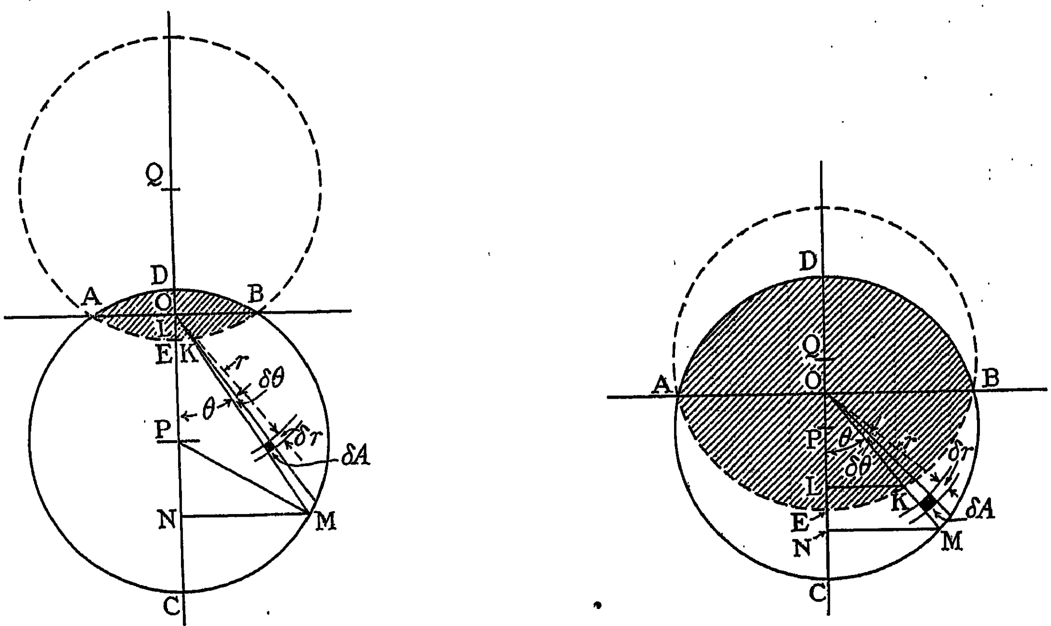
$$\frac{2e^2\nu}{\kappa}\gamma\frac{1}{R}$$

i.e. the "dispersing force" is inversely proportional to the size of the jet.

Now if I is the current in the jet, and Δ is the current density (which has been assumed uniform), we have

$$I=\nu e v$$
$$=\Delta\pi R^2$$

giving
$$\nu=\frac{I}{ev}=\frac{\Delta\pi R^2}{ev}$$



FIGS. 60 and 61.—Cross-section of jet.

Thus the dispersive force may alternatively be written

$$\frac{2e}{\kappa v}\cdot\frac{\gamma I}{R}$$

or
$$\frac{2\pi e}{\kappa v}\gamma\Delta R$$

(b) *The dispersion of the jet.*

The radial displacement of any electron after a small time interval is proportional to its acceleration and hence the force acting on it, since it starts from rest (the jet being assumed initially parallel). This displacement then is proportional to the radius, and as a result of this the electron maintains its relative position in the jet. Initially, therefore, the distribution of electrons throughout the cross-section of the jet tends to remain uniform during its expansion.

Assume that this condition holds for a ratio of expansion x, such that $R_t = xR_0$, where R_0 is the initial radius of the jet and R_t its radius after a time t

(measured from its parallel start). Then the law connecting the force on an electron with its radius remains true, and, for the bounding electrons of the jet,

$$\text{Force} = \frac{2e^2\nu}{\kappa}\cdot\frac{1}{R_0x} \quad (\text{since } \gamma = 1)$$

Now the acceleration of each of these electrons is

$$\frac{d^2}{dt^2}R_t = R_0\frac{d^2x}{dt^2}$$

Then
$$m_tR_0\frac{d^2x}{dt^2} = \frac{2e^2\nu}{\kappa}\cdot\frac{1}{R_0x}$$

or
$$x\frac{d^2x}{dt^2} = \frac{2e^2\nu}{\kappa m_tR_0^2}$$

This equation gives the required relation between the expansion ratio x and the time t.

On substitution of the radial velocity $(d/dt)R_t$ of the bounding electron the equation becomes of the

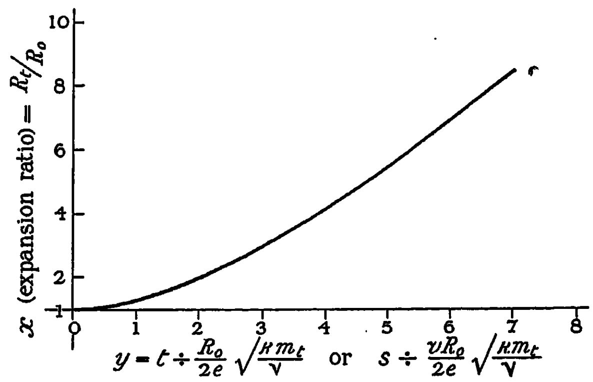

FIG. 62.—Scattering of an electron jet.

first order, and on subsequent integration it reduces to the form

$$t = \frac{R_0}{2e}\sqrt{\left(\frac{\kappa m_t}{\nu}\right)}\int\frac{1}{\sqrt{(\log_e x)}}\partial x$$

From this equation was obtained the relation between x and t shown by the curve (Fig. 62).

Now since the jet has a constant velocity v, we have $s = vt$, so that the equation may be written

$$s = \frac{vR_0}{2e}\sqrt{\left(\frac{\kappa m_t}{\nu}\right)}\int\frac{1}{\sqrt{\log_e x}}\partial x$$

where s is the distance travelled in time t, and therefore measures the position along the jet at which the expansion ratio is x. The curve therefore gives the relation between x and s, i.e. the shape of the jet.

(c) Characteristics of the phenomenon.

An inspection of the curve (Fig. 62) shows that it commences as a parabola and then tends to become a straight line; this leads to two useful results, which may also be deduced from the formulæ :—

(i) At the commencement of the jet's motion the radial velocity of the electrons is zero; hence their radius (position) and so their acceleration may be

assumed constant, under which condition their displacement (measured by $x - 1$) is proportional to the square of the time t and the distance s.

(ii) In the limit when R_t is large compared with R_0, the force and hence the radial acceleration of the electrons tends to zero, hence their radial velocity may be assumed constant; the displacement therefore becomes a linear function of the time t and distance s.

More important, perhaps, are other properties that are suggested by the formulæ :—

By substituting as, in Section (*a*) the alternative expressions for the linear electron density,

$$\nu = \frac{I}{ev} = \frac{\Delta_0 \pi R_0^2}{ev}$$

the constant in the equation takes the forms

$$\frac{R_0}{2}\sqrt{\left(\frac{v^3}{I} \cdot \frac{\kappa m_t}{e}\right)}$$

and

$$\frac{1}{2}\sqrt{\left(\frac{v^3}{\Delta_0} \cdot \frac{\kappa m_t}{\pi e}\right)}$$

(iii) If therefore the current density Δ_0 and the velocity v are kept constant, as may be achieved in a cold-cathode instrument by maintaining constant discharge conditions, the distance s travelled by the jet before a given ratio of expansion x occurs is independent of variations in the initial diameter $2R_0$ (controlled by the size of the diaphragm hole).

(iv) If, however, the current is made constant, the velocity v also remaining constant, the time t and the distance s taken to reach a given fractional expansion x are proportional to the initial diameter ($2R_0$) of the jet, i.e. *the smaller the jet, the faster it grows.*

(v) If the initial diameter is constant but the current in the jet is varied, the time t and the distance s for a given value of x vary inversely as the square root of the current I, i.e. *the more intense the jet, the faster it grows.*

(vi) With the initial diameter and the current held constant, the time t for a given x varies directly as the square root of the velocity v; but the distance s varies as the 3/2 power of the velocity, i.e. *the slower the jet, the faster it grows.*

THE ELECTRICAL CONDUCTIVITY OF CERTAIN LIGHT ALUMINIUM ALLOYS AND COPPER CONDUCTORS AS AFFECTED BY ATMOSPHERIC EXPOSURE.*

By Professor ERNEST WILSON, Member.

(*Paper first received* 21*st April, and in final form* 20*th July*, 1925.)

SUMMARY.

The paper deals primarily with the effect which atmospheric exposure has upon the electrical conductivity of certain light aluminium alloys, the period of exposure extending to 24 years. Twenty-five alloys of aluminium with the metals copper, nickel, manganese and zinc in amounts not exceeding 1 or 2 per cent have been tested at intervals for electrical resistance, whence the variation in conductivity has been found. In the case of copper alone, or copper and manganese jointly, the conductivity continuously diminishes in value, whereas with copper and nickel, or copper and zinc, or combinations of all three of these, the conductivity at first decreases, and then in some cases increases in a remarkable manner, finally attaining a more or less constant value. The factors concerned are the specific resistance of the alloy and the loss of metal due to corrosion, and it has been found possible to separate the total variation into these two classes. Some further work deals with the exposure of copper conductors.

This paper brings together the results of a series of exposure tests of certain light aluminium alloys and copper conductors which have been in progress since 1901, and which have been reported upon from time to time at meetings of the British Association.† The physical properties of the aluminium alloys were dealt with in a paper read before the Institution,‡ to which reference should be made for further details. All the specimens are in the form of wire 0·126 inch (3·2 mm) diameter, and have been exposed on the roof of King's College, London. In Table 1, which is taken from the Institution paper, will be found the composition and certain other data relating to the alloys before exposure. The tests to be now considered consisted in measuring the electrical resistance of each wire in the months of July or August in any one year, and reducing the resistance to 15° C. by aid of the temperature coefficient given in Table 1, the assumption being that the coefficient has remained constant.

A specimen of each alloy has been preserved in a box in the Laboratory, and the variation of specific resistance of certain of these specimens is given in Table 2. All these specimens are bright, with the exception of one or two which are very slightly clouded, and they are all in good condition. None of them was annealed, as was the case in certain of the exposed wires.

Let R_0 be the electrical resistance, ρ_0 the specific resistance, and r_0 the radius of the wire before exposure, and let R_t, ρ_t, r_t be the same quantities at time t during exposure. Then $\pi r_t^2/\rho_t = (\pi r_0^2/\rho_0)(R_0/R_t)$. In the graphs the values of R_0/R_t are plotted against the time of exposure t in years. The variations in the ordinate are due to variations in the ratio of the effective conducting area to the effective specific resistance. In the case of an unevenly corroded wire the radius r has no very obvious meaning, and it does not follow that the specific resistance has a constant value over the conducting cross-section.

It should be noted that all the specimens of Table 1 were raised to about 100° C. in an oil bath during the determination of the temperature coefficient; in addition, specimens 12 to 24 inclusive were annealed before exposure at a temperature of 435° C. The consequent increase in conductivity varied by small amounts to 3·8 per cent in the case of alloy 22. In the paper the conductors are grouped according to the elements added to the aluminium.

Further tests have been made to separate the effects due to loss of metal by corrosion from those due to variation of specific resistance. The initial volume of unit length of the conductor is $\pi r_0^2 = a_0$, say, and the volume of the corroded portion of unit length at time t is the weight of the metal lost divided by its specific gravity, equal to b_t, say. Then the ratio

$$\frac{R_t}{R_0} = \frac{\rho}{\rho_0} \times \frac{a_0}{a_0 - b_t}$$

where the first term deals with the increase in resistance due to variation of specific resistance, and the second term deals with the increase due to diminution of volume. Care was taken when removing the corroded portion not to go beyond the point at which the electrical resistance of the conductor would be increased. The resistance of a known length of the conductor and its weight were then determined. With this information and the other known data the figures given in Table 4 have been worked out, and the last two columns give the calculated and observed values of the ratio R_t/R_0.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

(I) Commercial Aluminium.

Specimen 25, described as "commercial aluminium," contains 99·55 per cent of aluminium and in this respect would appear to correspond to the quality of aluminium now normally supplied for electrical conductors. The term "commercial aluminium" now has a particular significance in the aluminium industry and signifies a metal of somewhat lower purity, such as is normally used for general purposes. Metal for electrical purposes, having a purity of 99·5 per cent of aluminium and over, is no longer described as "commercial aluminium."

Table 2.

Alloy	Specific resistance at 15° C. 1901	1925	Difference
	microhms per cm³		per cent
4 unannealed	2·88	2·893	+ 0·45
8 unannealed	3·24	3·161	− 2·44
22 unannealed	3·41	3·306	− 3·05
23 unannealed	3·49	3·420	− 2·01
25 unannealed	2·773	2·773	nil

It is interesting to compare the properties of specimen 25 with those of the present-day wires supplied for electrical purposes, as given in the recently issued British Standard Specification No. 215. The following table summarizes the differences for wires of 0·126 inch diameter:—

	Specimen 25, 1901	B.E.S.A. Standard, 1925
Tensile strength	28 200 lb./sq. in.	26 000 lb./sq. in.
Elongation	1·86 per cent (on 13·8 in.)	2·0 per cent (on 10 in.)
Specific resistance at 60° F.	2·7795 microhms/cm³	2·8056 microhms/cm³
Specific gravity	2·715	2·705

The chief difference lies in the low value of the specific resistance, which is all the more remarkable in that the tensile strength of specimen 25 is higher than that of the present-day standard. Using the formula given in the British Standard Specification connecting the specific resistance R with the tensile strength T_p, viz.

$$R = 2 \cdot 7320 + 2 \cdot 8289 \times 10^{-6} T_p$$

the specific resistance of the specimen should be 2·8112 microhms/cm³ at 60° F., as against the actual value of 2·7795. The latter therefore appears low, but it was confirmed by tests made at the National Physical Laboratory at the time, under the date 9th July, 1902. This figure is fractionally higher than the one given in the Institution paper, which was obtained from another portion of the same wire. It would appear, therefore, that though apparently comparable as regards purity, specimen 25 differs in important respects from present-day electrical wires.

Although not properly coming under the copper-aluminium group the curve obtained (25) for this specimen is plotted in Fig. 1. Another specimen (25A) from the same coil and first exposed in 1911 has diminished in conductivity at about the same rate, and has slightly increased in conductivity during the rest of six years in the Laboratory (Table 3).

Referring to Table 4 it will be seen that the specific resistance of specimens 25A and 25 has increased, and that the increase in resistance is largely due to loss of metal. Great care was taken to establish the recorded increase in specific resistance, and a second piece of 25A was tested and gave a value of $2 \cdot 914 \times 10^{-6}$ at 15° C. The unexposed specimen (25) which has been preserved in the Laboratory shows no alteration in specific resistance (Table 2). On removing the corroded portion the metal is perfectly sound. An examination of the corroded portion, kindly made by Prof. E. F. Herroun, F.I.C., shows that it consists mainly of alumina and metallic aluminium. It also contains sulphate in appreciable quantity, and a trace of chloride, also traces of iron probably derived in part from the emery paper, but no zinc or nickel.

(II) Aluminium-Copper.

It will be seen in Table 1 that specimens 16, 4, 13, 14 and 15, contain copper in ascending order of magnitude, and 24 is an aluminium-copper alloy containing a definitely larger proportion of iron. Referring to the curves in Fig. 1, which are numbered to correspond to the specimen numbers in Table 1, it is seen how greatly the slope increases with the percentage of copper. The deterioration of alloy 15 progressed so rapidly that its useful life was reduced to a few years, and it is followed by 14 and then 13. Specimens 4, 16 and 24 have steadily diminished in conductivity to about the same extent.

Referring to Table 4 it will be seen that these three specimens have lost comparatively little metal by corrosion. Their initial resistance, R_0, compares favourably with that of 25, and the final resistance R_t is in the case of specimens 16 and 4 considerably better than that of 25.

It is interesting to note that the unexposed alloy 4 (Table 2) shows practically no alteration in specific resistance.

(III) Aluminium-Nickel-Copper.

Specimens 7, 8, 20, 21 and 22, forming this group are all in good condition; in fact some of them seem

to be almost as good mechanically as when first exposed in 1901. Alloys 21 and 22 are remarkable on account of their high breaking load, and 22 differs from the rest in that its temperature coefficient of electrical resistance is about one-half that of the others.

that there is initially a small increase in conductivity. In alloy 22, conductivity has dropped in seven years to about 84 per cent, and, judging from the behaviour of the copper alloys (Fig. 1), one might have thought that this alloy (22) was so far deteriorated as to be of

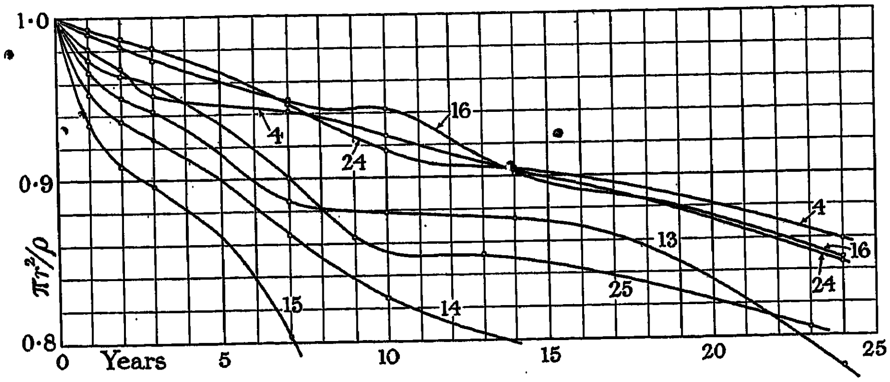

FIG. 1.—Aluminium-copper.

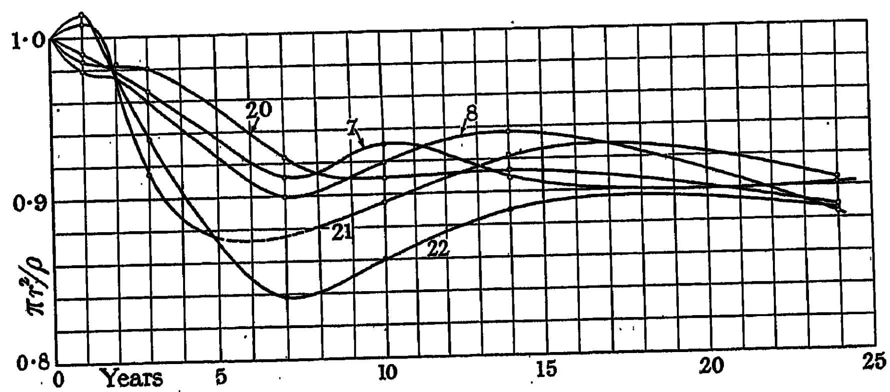

FIG. 2.—Aluminium-nickel-copper.

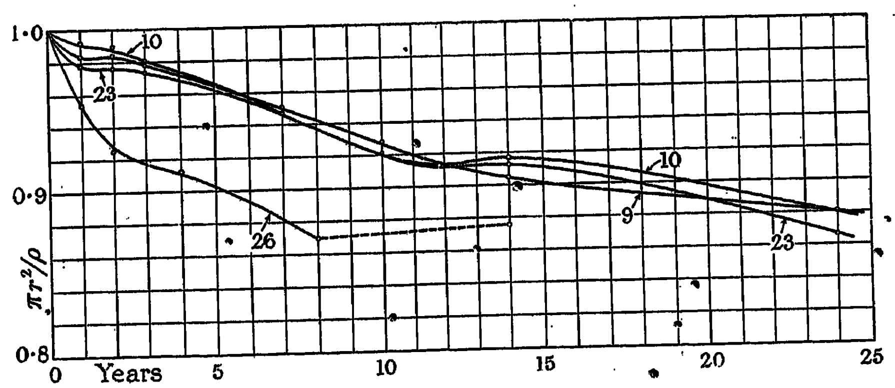

FIG. 3.—Aluminium-manganese-copper.

The type of curve in Fig. 2 differs from that in Fig. 1 in that the initial fall is followed by a remarkable recovery. It would appear that, in addition to corrosion, the structure of the alloy has changed in such a manner as to increase its conductivity. This effect is so strongly marked in the case of alloys 21 and 22,

little use. This is not the case and the specimen after 24 years' exposure is not only in good condition but has a conductivity 88·5 per cent of its original value.

The unexposed specimens 8 and 22 (Table 2) show that specific resistance has diminished to the extent of 2·44 and 3·05 per cent respectively. It may be that

under the exposed conditions the diminution is more severe, and if this were so it might throw light upon the type of curve shown in Fig. 2.

It will be seen in Table 4 that all the specimens with time, and there is no rapid fall followed by a rise, as in Fig. 2. The unexposed specimen 23 (Table 2) shows an increase in conductivity amounting to 2·01 per cent in 24 years. The increase in resistance (Table 4)

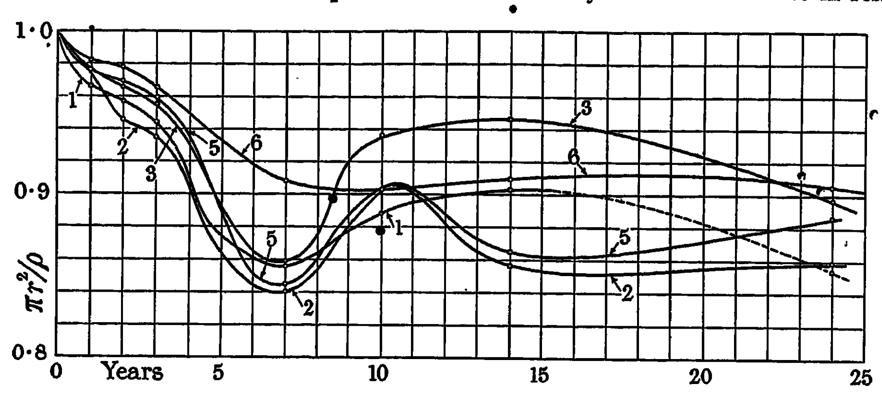

FIG. 4.—Aluminium-zinc-copper.

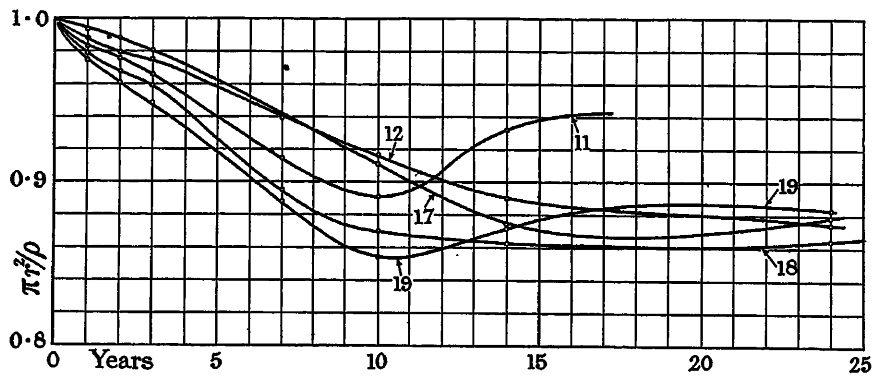

FIG. 5.—Aluminium-zinc-nickel-copper.

forming this group have suffered but little by loss of metal. Nos. 7, 8 and 20 are exceedingly fine alloys as none of them has suffered great variation in conductivity (Fig. 2). No. 7 has an initial resistance, R_0, due to loss of metal is very small in the case of all the conductors forming this group. No. 10 is the best so far as the initial and final resistances (R_0, R_t) are concerned.

TABLE 3.

Values of R_t/R_0 at End of Stated Intervals.

Metal	1911–12	1911–13	1911–15	1915–16	1915–19	1919–25
Copper (annealed)	1·012	1·020	Specimen missing	—	—	—
Copper (annealed)	—	—	—	1·0054	1·0224	0·9954
Copper (hard-drawn)	—	—	—	1·0002	1·0187	0·9958
				1911–16	1911–19	
(26) Duralumin	1·051	1·082	1·096	1·110	1·150	0·9941
(25A) Aluminium	1·037	1·044	1·073	1·102	1·150	0·9977

slightly higher than that of 25, but the final resistance, R_t, is smaller.

(IV) ALUMINIUM-MANGANESE-COPPER.

The alloys 9, 10 and 23 (Fig. 3) like the low-percentage copper alloys (Fig. 1) steadily diminish in conductivity

The actual specimen of duralumin (26) exposed has not been chemically analysed as in the case of all the other alloys, and it is stated to contain from 3·5 to 5·5 per cent copper, 0·5 to 0·8 per cent manganese, and about 0·5 per cent magnesium. After eight years' exposure its conductivity has fallen to 87 per cent

	18	24	3·245	0·07965	40·74	3·569	0·002896	46·50	0·07675	1·100	1·038	1·142	1·156
	19	24	3·205	0·07933	40·40	3·555	0·001769	45·84	0·07756	1·109	1·023	1·134	1·130
	11	24	3·48	0·07949	43·80	3·787	0·001514	48·56	0·07798	1·088	1·019	1·109	1·109

of its initial value, and shows no sign of recovery. It is possible that the high copper content is responsible for this. The dotted portion of curve 26 indicates the slight recovery due to rest in the Laboratory (Table 3). It was pointed out (British Association Report, 1913) that this alloy becomes brittle on exposure, and this is evidence that it undergoes severe physical change.

(V) Aluminium-Zinc-Copper.

All the alloys (Fig. 4), with the exception of 6, have shown an initial fall in conductivity followed by a rapid recovery. Alloy 6 with small loss of metal (Table 4) has maintained a very steady conductivity (Fig. 4) but its initial and final resistances (R_0, R_t), are rather high. No. 1 is superior in this respect, but its conductivity suffers considerable variation during exposure, and it has suffered a greater loss of metal.

(VI) Aluminium-Zinc-Nickel-Copper.

The initial fall in conductivity (Fig. 5) is more gradual, and in the case of specimens 12, 17 and 18 a fairly stable condition is ultimately attained. Specimens 11 and 19 exhibit a considerable increase in conductivity after having passed the minimum.

Alloy 11 has maintained a relatively high conductivity, and the increase in resistance due to diminished volume is small. With the exception of 17, the values of R_0 and R_t are somewhat high. The loss of metal throughout is small, and increased specific resistance largely accounts for the increase in resistance.

(VII) Copper.

The results of the copper exposure tests are given in Table 3. The specimens are about 80 ft. long and have a diameter of 0·126 inch (3·2 mm), and were supplied as high-conductivity copper in the annealed and hard-drawn conditions. The percentage increase in electrical resistance during the first year is greater in the annealed than in the hard-drawn state, and after four years' exposure the hard-drawn wire has a somewhat lower percentage increase, the figures being 2·24 and 1·87 respectively. The specimens were then submitted to a rest of six years in the Laboratory, being loosely coiled up, and during this period a small diminution in electrical resistance has been observed.

The author wishes to express his thanks to the British Aluminium Company, Ltd., for their kindness in supplying the note on what is now meant by "commercial aluminium."

THE TWO-SPEED CASCADE INDUCTION MOTOR.*

By A. H. M. ARNOLD, B.Eng., Student.

(*Paper first received 23rd February, and in final form 5th May,* 1925.)

SUMMARY.

The general conditions of operation of two motors in direct and differential cascade are considered, with special reference to the possibility of the set running at a speed near the synchronous speed of the primary machine, while still connected in cascade.

Hunt's cascade motor is next described. The theory of the superposition of two fields in one magnetic circuit is given, and vector diagrams are drawn of the M.M.F. to be produced by the rotor windings at each point. The superposition of two currents of different frequency in the stator windings is next dealt with, and an account is given of the experimental work carried out to verify this theory, by means of oscillograph records of the currents flowing in the various coils of the stator windings of the motor tested.

TABLE OF CONTENTS.

The research carried out is based on the paper by L. J. Hunt, entitled "The Cascade Induction Motor" (see *Journal I.E.E.*, 1914, vol. 52, p. 406).

(I) SPEED OF CASCADE MOTORS, OR SPEED OF TWO MOTORS CONNECTED IN CASCADE.

The theory of cascade running is well known, and the formula by which the synchronous speed of a cascade set may be determined is given below.

Let R be the speed in revolutions per second (r.p.s.) of the two machines at synchronous speed. The motor connected to the supply mains will be referred to as the primary motor, whilst the other will be referred to as the secondary motor.

Let P_1 and P_2 = the numbers of pairs of poles for which the motors are wound.

N = the frequency of the supply circuit.

Then the synchronous speed of the set is

$$R = \frac{N}{P_1 + P_2}\ \text{r.p.s.} \quad \text{or} \quad \frac{60\,N}{P_1 + P_2}\ \text{r.p.m.}$$

If two of the leads from the primary rotor to the secondary stator are interchanged, so that the secondary field rotates in the opposite direction, then $R = N/(P_1 - P_2)$ r.p.s. This is known as "differential cascade." *

It should be noted that in this latter case the torques of the two motors are opposed to each other, so that the resultant torque is equal to the difference of the two torques. The performance of the set is, therefore, generally very poor.

If P_1 is less than P_2, rotation takes place in the direction of the magnetic field of the secondary machine. The frequency of the currents in the rotor of the primary machine and the stator of the secondary machine is then higher than the supply frequency, with resultant high iron losses.

If P_1 is greater than P_2, rotation takes place in the direction of the magnetic field of the primary machine, and a stable speed is reached just below the synchronous speed of the primary machine. Above the synchronous speed of the primary machine there is a zone where the torque of both machines becomes negative, and regeneration of power takes place. Beyond this zone the primary machine begins to motor again, and its torque finally predominates over the negative torque of the secondary machine and a stable speed is reached below the synchronous speed of the set. It is therefore evident that, with this method of connection, the motors must be brought up to speed by external power. This may sometimes be done by running the machine with the smaller number of poles as a plain induction motor and then, when the set has passed the generating zone, changing over the connections to differential cascade. The advantage of this method of connection is that the frequency of the currents circulating between the two machines is lower than with the first method. Differential cascade sets have a very limited application.

When two motors are connected in direct cascade, it is also possible for them to run at the synchronous speed of the primary machine, but in this case the speed is higher than cascade synchronous speed, and when the set is started up from rest it reaches a stable speed just below cascade synchronous speed and therefore does not increase its speed further. The point is of importance, however, if, as in most cases, the set has change-over switches, so that the primary machine can run as a plain induction motor at a speed near the primary synchronous speed, while the secondary machine is disconnected electrically. (If $P_1 = P_2$, then both machines may be connected in parallel to the mains.) If, while running at this higher speed, the switch is changed over to cascade connection, provided that the resisting torque is below a certain value the

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

* See C. DELLA SALDA: "Induction Motors in Differential Cascade," *Elettrotecnica*, 1922, vol. 9, p. 266.

set will continue to run at the higher speed, instead of dropping to the cascade speed. This applies equally, of course, to Hunt's two-speed cascade motor, the higher speed being the speed of the machine as a simple induction motor. On light loads, changing over the connections will not bring the speed of the machine down to cascade speed.

The theory of this will now be considered, and an actual example will be taken to illustrate it. Consider a 50-cycle, 4-pole–4-pole cascade set running at about 1 450 r.p.m. with both machines in parallel on the mains. The connections are now changed over, so that one machine is supplied from the rotor of the other. The frequency of the currents now flowing in the stator of the secondary machine will be about 1 cycle, or the speed of magnetic field will be 50 r.p.m., while the rotor is rotating at 1 450 r.p.m. The slip is therefore

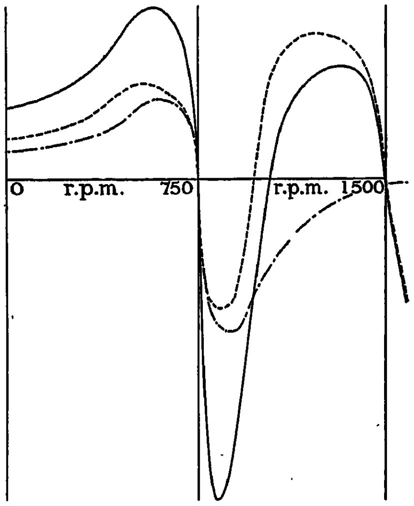

FIG. 1.—Shaft torque of two motors connected in direct cascade. Synchronous speed of cascade set = 750 r.p.m.; synchronous speed of primary motor = 1 500 r.p.m.

negative, so that the torque becomes negative and regeneration takes place. This causes an increase of slip for the primary machine, i.e. a reduction in speed of the set, and the torque of the primary machine rises until it is sufficient to offset the negative torque of the secondary machine. It should be noted that, as regeneration takes place, no extra power is required from the mains beyond that necessary to supply the extra copper losses involved, so that the secondary machine really acts simply as an impedance and increases the losses of the set. It receives its power through the shaft from the primary machine and regenerates electrical power back to the rotor windings of the primary machine. As, however, the primary machine has now to offset the negative torque of the secondary as well as to overcome the external torque, the slip will increase in order to provide the additional torque. The maximum external torque which the machine is capable of overcoming will be reduced, and if the external torque exceeds this, the speed will drop to cascade speed, when both motors will once more exert a positive torque and a stable speed will be obtained (see Fig. 1). Methods have therefore to be devised of lowering the speed of a cascade set from its high speed to its cascade speed, if the load is not sufficient to accomplish it automatically when the connections are changed over. With moderate loads the speed may be lowered by inserting resistances into the rotor circuits until the increased slip makes the speed equal to cascade speed, when the change-over may be effected. If the load is very small, or if there is no load at all, the amount of external resistance required may be excessive. In this case the only way of lowering the speed is to switch off the main supply, change over the connections, and then, when the speed has fallen to cascade speed, switch in again.

Fig. 1 also shows that with cascade connections there

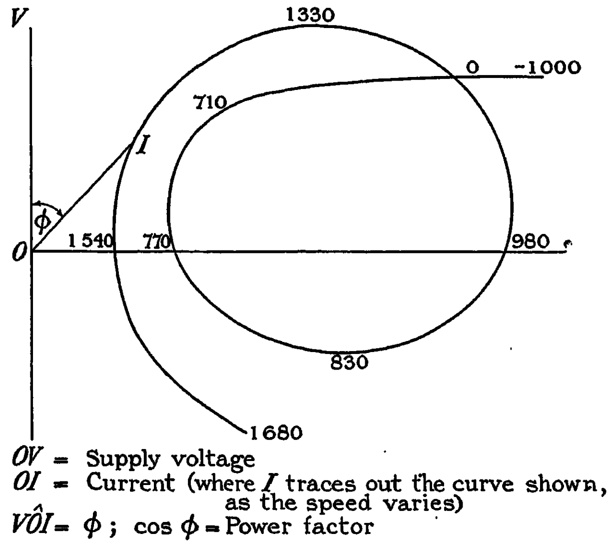

FIG. 2.—Circle diagram of two motors connected in direct cascade. Synchronous speed of cascade set = 750 r.p.m.; synchronous speed of primary motor = 1 500 r.p.m. The figures indicate the approximate speed in r.p.m. at various points of the curve.

are two zones of regeneration, and Fig. 2 shows the power factor of regeneration and the current. In the upper speed zone (above 1 500 r.p.m.) regeneration at a better power factor and with a smaller slip may be obtained by disconnecting the secondary machine and using the primary machine as a plain induction generator.

In the lower-speed zone (above 750 r.p.m.) the power factor of regeneration is very poor, and there is the additional disadvantage of the danger of the machine passing the peak of the regeneration curve, when it would immediately run up to double its speed unless the driving unit were capable of checking it.

All the above remarks apply equally well to a cascade set of two machines, or to Hunt's cascade motor. Hunt's motor will now be considered in more detail.

(2) THEORY OF HUNT'S CASCADE MOTOR.

The disadvantages of the ordinary cascade set are low power factor and low output for a given amount

of machinery. The reasons for this are well known, but are recapitulated here very briefly. The mains have to supply the magnetizing current for both machines, whilst the output of the two machines in cascade is less than the output of one machine at normal speed. This results in a small load current and large magnetizing current, thus giving a poor power factor.

The reason for the reduced output is that the circle diagram of the two motors in cascade is very much reduced in size, since the magnetizing current is increased to double, as stated above, whilst the short-circuit current of the set is considerably less than for one machine alone. This gives a small diameter to the circle and consequently reduced output.

In Hunt's motor the power factor at cascade speed is poor, as is that of two motors in cascade, and the circle diagram is very similar in size. The chief advantage lies in combining the two machines in one frame and thus reducing the cost of construction and the space occupied. The copper losses are considerably reduced owing to the cancelling out of the equal currents which tend to flow in opposite directions in the superposed windings, and the efficiency is therefore found to be higher than that of an equivalent cascade set of two machines.

Although the power factor of a cascade set or of Hunt's motor at cascade speed is poor compared with that at the higher speed, it is not necessarily bad when compared with the power factor of an ordinary induction motor running at the lower speed, since the magnetizing current increases with the number of poles. The motor under test was a comparatively high-speed machine (500 r.p.m. cascade speed) and therefore does not compare so favourably with a plain induction motor at the same speed as a lower-speed machine would do. With abnormally low speeds the power factor is sometimes better than that of an ordinary induction motor running at the same speed.

It should first be noted that a cascade set will run equally well if the rotor windings of the primary are connected to the rotor windings of the secondary and the stator of the secondary short-circuited. In this case the connections must be so made that the magnetic field in the secondary rotates in the opposite direction to the field in the primary, as it will be necessary at synchronous cascade speed for the field to be stationary relative to the stator windings of the secondary. This is obtained when the rotor rotates in one direction at a speed equal to the speed of the field in the other direction.

With this method of connection slip-rings are abolished and starting resistances may be inserted in the stator of the secondary, the two rotor windings being permanently connected. This, of course, applies only if cascade speed alone is required; if, in addition, the normal induction-motor speed is required, slip-rings will be necessary to obtain it.

The next stage in Hunt's motor is to combine the two machines in one. This can be considered in two parts, the rotor and the stator.

(*a*) *The rotor.*—The rotor will not be dealt with at length here, as no investigation upon it was carried out. In the machine tested, the rotor has a winding in which it is impossible to get tappings without damaging the windings and insulation, so that the only data obtainable were of the current flowing to the slip-rings with the machine running at the higher speed. This was found to be a fairly sinusoidal wave with a few ripples, as will be seen from Fig. 3.

The rotor is dealt with at length in Mr. Hunt's paper, and also in a new and more effective way in Mr. Creedy's.

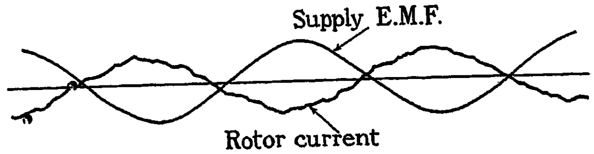

FIG. 3.—Motor at non-cascade speed and no load.

This record was taken with two of the slip-rings short-circuited through the oscillograph to the third ring.

paper.* A short résumé of Mr. Creedy's line of reasoning will be given here, in order to maintain the continuity of the report, but it should be clearly understood that no experimental verification was obtained, beyond the fact that the motor operated satisfactorily at both the cascade speed and the higher speed. An attempt was made to get an idea of the distribution of the flux in the air-gap. This will, however, be dealt with later.

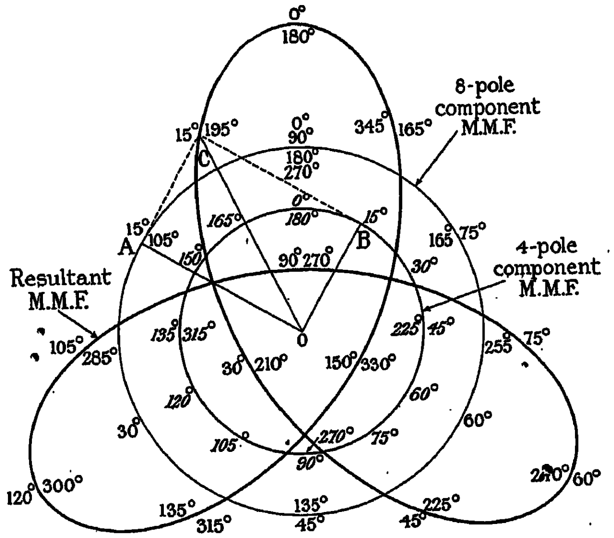

FIG. 4.—Vector diagram of M.M.F. of 8-pole–4-pole rotor. Positions round rotor in degrees are marked on curves, e.g. at 15° from starting point OA = vector representing in phase and magnitude 8-pole component M.M.F.; OB = vector representing in phase and magnitude 4-pole component M.M.F.; and OC = vector representing in phase and magnitude resultant M.M.F.

To simplify the explanation, an actual case will be taken, and the one considered will be that of the motor on which the experiments were carried out. This machine was an 8-pole–4-pole machine, running at 8-pole speed (750 r.p.m.) for one speed, and at cascade or 12-pole speed (500 r.p.m.) for the other speed. During cascade running, the currents in the stator windings produce an 8-pole field rotating at 750 r.p.m.

* *Journal I.E.E.*, 1921, vol. 59, p. 511.

The rotor winding if wound for 8 poles will have currents induced in it, and if this is connected in series with another rotor winding wound for 4 poles it will produce a 4-pole field rotating in the opposite direction. Actually neither field exists separately, but only a compound field. If the nature of this field is discovered, then a single rotor winding may be developed to produce it, and the cascade effect will be obtained with only one winding.

Space/time vector diagrams must now be introduced. If for each point on the rotor a vector be drawn representing the value and time-phase of the flux at that point, then a curve may be drawn joining the ends of these vectors to show the maximum (or R.M.S.) value of the flux at any point on the rotor and also its time-phase with respect to other points. As an example, take a 4-pole field distributed in space according to a sine wave. As we proceed round the rotor, the vector

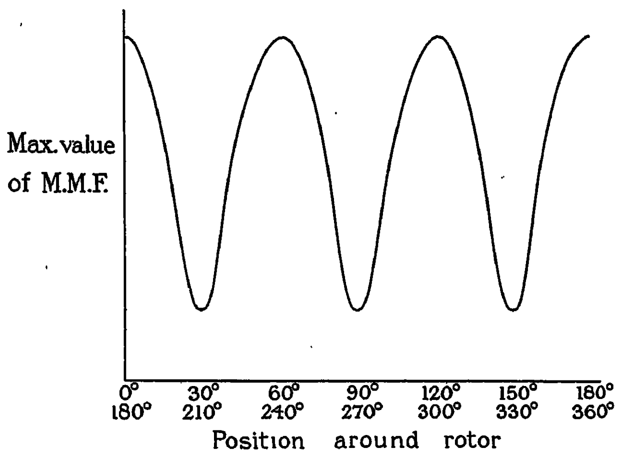

FIG. 5.—Diagram showing how the maximum value of the M.M.F. varies round the rotor for an 8-pole–4-pole field. It does not show the phase relationships of these M.M.F.'s, which must be obtained from Fig. 4 as explained there.

representing the flux maintains the same value but completes a circuit of the diagram twice while we go round the rotor once. The flux distribution is therefore represented on this diagram by a circle, and each point on the circle will correspond to two distinct points on the rotor, since there will be two points on the rotor, 180° apart, which have the same value of the flux at the same instant. Similarly, with an 8-pole field a circle will be obtained, each point of which corresponds to four positions on the rotor. It can be seen, therefore, that the flux in a sinusoidal field may be represented by a vector, which rotates p times in one circuit of the rotor, where p = number of pairs of poles. These vectors can be compounded similarly to other vectors, and in our case let us compound an 8-pole field and a 4-pole field rotating in opposite directions.

Starting from a point where the two fields have their maximum value together, we mark this by a vector equal to the sum of the two fields, drawn vertically upwards. Proceeding, say, 15° round the rotor, the 4-pole vector will have rotated through 30° in one direction, and the 8-pole vector 60° in the other direction. Compounding these two, we get the actual value of the flux at that point in time and magnitude. Proceeding thus in steps of 15°, a series of points may be plotted which may be joined up in a smooth curve. This curve will be found to repeat itself in the second half of the rotor. A reproduction of the curve is given in Fig. 4. The shape will depend to a certain extent on the relative values of the 8-pole and 4-pole fields, but the general form will remain unaltered, and the

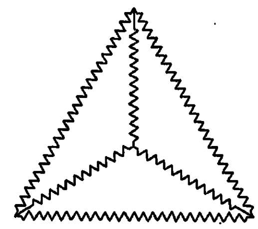

FIG. 6.

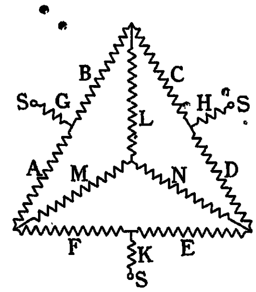

FIG. 7.

chief feature of the rotor at once stands out. This is, that the ampere-conductors at different parts of the rotor will be different. A winding may now be devised to conform as closely as possible with the curve below, and Mr. Creedy gives examples of these. They are thought out without any reference to the two component fields, and in conformity with the diagram, so as to obtain the required resultant field.

Mr. Hunt's treatment is somewhat different, and consists of taking the two windings, superposing them,

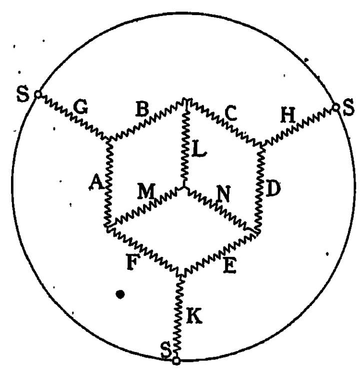

FIG. 8.

and then cancelling the bars which carry currents of equal value in opposite directions. This method is complicated and is not so universally applicable as Mr. Creedy's.

Having constructed a winding in accordance with the above M.M.F. diagram, the rotor will operate satisfactorily at cascade speed. When, however, the machine is required to run at the higher speed it is necessary to distribute the M.M.F. sinusoidally around the rotor so as to give an 8-pole field. As the slots in a motor are all of the same size, those slots which only carry a few bars (that is, where the M.M.F. required for cascade speed is low) are filled with idle bars. When the higher

speed is required, these bars are connected into the rotor winding by short-circuiting the slip-rings (through resistances at first) and thus effecting an even distribu-

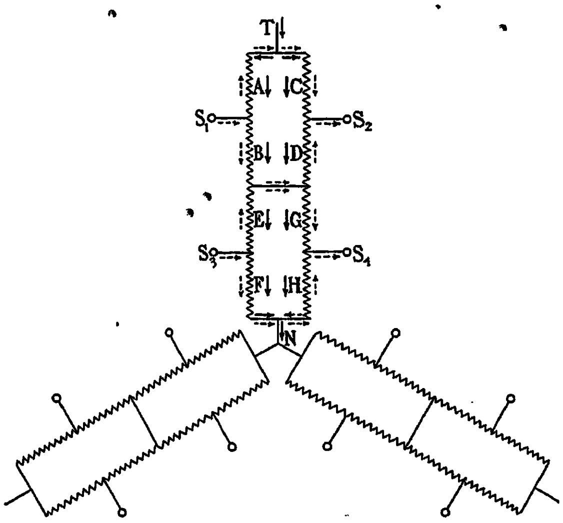

FIG. 9.—Key diagram of stator winding.
Primary currents ⟶ Secondary currents - - →

tion of M.M.F. The method of connecting these idle bars is clearly shown in Mr. Hunt's paper.

The normal cascade winding for Mr. Hunt's motor is one end and to the middle parts of the delta winding at the other end. The resultant winding is shown in Fig. 7. When the slip-rings are short-circuited the phases of the currents in the various branches are altered, and the resultant winding becomes four inter-connected star windings (see Fig. 8). A circle shows the points short-circuited by the slip-rings. Corresponding coils in Figs. 7 and 8 are lettered. The reasoning by which Mr. Hunt shows this winding to give the required M.M.F. is best followed in his paper.

(*b*) *The stator.*—The treatment of the stator winding is quite different and will be considered in detail, and an account will be given of the experimental verification of the theory of this winding by means of oscillograph records of the currents in the various branches of it.

The stator winding in the machine under test was star-connected and was wound for 8 poles. Each phase consisted of two circuits in parallel. Three-phase currents were supplied to this stator from the external supply at supply frequency, i.e. 50 cycles, and circulated in the windings in the usual way. These currents produced an 8-pole field, and the currents induced by this 8-pole field in the rotor reflected back a 4-pole field in the manner described in the previous section.

The stator has now to be so designed that the E.M.F.'s induced by this 4-pole field may be able to circulate currents in the windings without affecting the high-

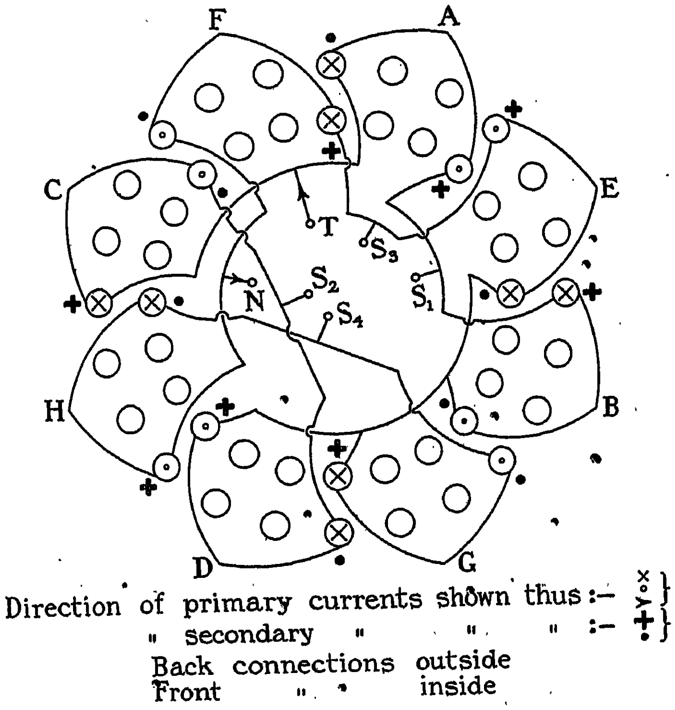

FIG. 10.—Stator winding diagram.

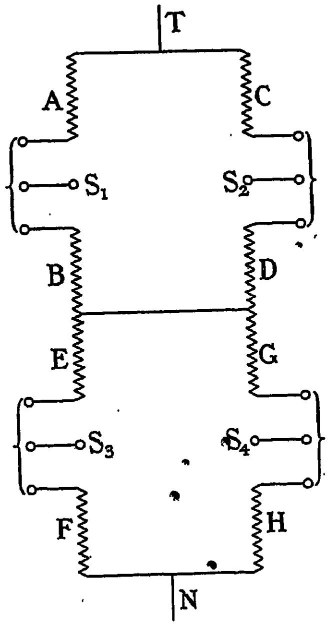

FIG. 11.—Experimental tapping points, stator phase.

a star-mesh winding, as shown in Fig. 6. This winding will produce the required magnetomotive force as Mr. Hunt shows, although others will do so also.

Mr. Hunt connects the idle bars to the slip-rings at frequency supply currents. Tappings must also be obtained for the insertion of resistances during starting, and these tappings must be taken from points at which there is no P.D. due to the supply current. This at

once gives the reason for the stator winding having parallel circuits, and the key diagram for the actual stator winding is given in Fig. 9.

Since the stator is wound for 8 poles, the coils will be only half-pitched with respect to the 4-pole field. Consequently, adjacent coils of the same phase will have their maximum E.M.F. 90° displaced from each other in time, so that in order to use the windings to the best advantage, two-phase currents will have to be arranged for. In the winding, coils A, B, C and D alternate with coils E, F, G and H (see winding diagram, Fig. 10), so that the secondary currents in A, B, C and D are in phase with each other and 90° out of phase with the currents in E, F, G and H. The windings are strapped across at the mid-point, as shown in Fig. 9, and are so arranged that the secondary currents flow from the tapping points [s_1 s_3] on each side through the windings and straps to the tapping points [s_2 s_4] on the other side. For starting, these tapping points are connected through resistances, and during normal running they are short-circuited in pairs [s_1 s_2 ; s_3 s_4]. Since the points at which tappings are taken are equipotential with respect to the supply current, they will not cause any disturbance to this current.

The main current is shown by full arrows in the key diagram (Fig. 9) and winding diagram (Fig. 10), and the secondary currents by dotted arrows. It will be seen that the two diagrams agree. The directions of currents in the winding diagram are obtained from the usual rule for magnetic fields. For operation at non-cascade speed it is immaterial whether the starter tapping points are short-circuited or open-circuited. At non-cascade speed the stator only carries the high-frequency supply current, the machine operating as an ordinary induction motor. The tapping points are, therefore, equipotential points, and no change is made in the electrical conditions by short-circuiting them.

TABLE.

Particulars of Motor on which the Investigations were Made.

Hunt's two-speed cascade motor, manufactured by Messrs. Sandycroft, Ltd., Chester.

200 volts	50 cycles	3-phase
10 b.h.p.	710 r.p.m.	30·5 amps.
6$\frac{3}{4}$ b.h.p.	480 r.p.m.	21·5 amps.

No. of stator slots = 72.

OSCILLOGRAPH INVESTIGATION.

An oscillograph investigation of the currents flowing in the various coils of the stator winding was made in order to confirm the theory outlined in the paper. Tappings were taken from the stator winding and brought out to a terminal board in accordance with Fig. 11. Each group of these terminals was normally short-circuited, but by disconnecting the short-circuiting strap the current in any coil could be sent through the oscillograph before returning to the machine.

On no load at cascade speed these currents were found to be nearly pure sine waves. As the high-frequency magnetizing current is very large at no load compared with the low-frequency secondary current, the resultant stator current is practically identical with the magnetizing current.

On full load the low-frequency current is comparable in magnitude with the high-frequency current, and the resultant current differs considerably from a sine wave. As the frequencies were very different, during one complete period of the high-frequency current the low-frequency current did not alter much, so that the resultant wave approximated to a sine wave with a constantly shifting centre line. A curve drawn through successive maximum points of the resultant wave thus

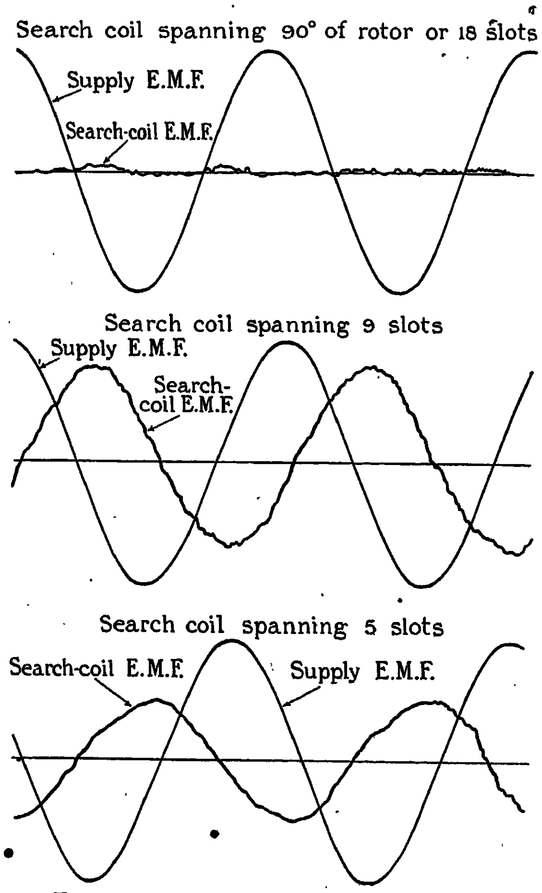

FIG. 12.—Motor on load at cascade speed.

gave a very fair approximation to the low-frequency current. Owing to unevenness in the belt drive to the load, the high-frequency current was not constant and thus the curve drawn through the maximum points was not a true representation of the low-frequency current. It was sufficiently accurate to enable the maximum and minimum points to be approximately determined, but it was useless to analyse the harmonics, as these varied from point to point.

Reproductions of the secondary currents analysed from the film records, and also a portion of the film, are shown in the oscillographs Figs. 13 and 14. It was found that the secondary currents in coils A, B, C and D were in phase with one another and in quadrature with

the currents in coils E, F, G and H. The primary currents were in phase with each other in all the coils. This confirms Mr. Hunt's theory.

Search coils were wound on the stator spanning 18,

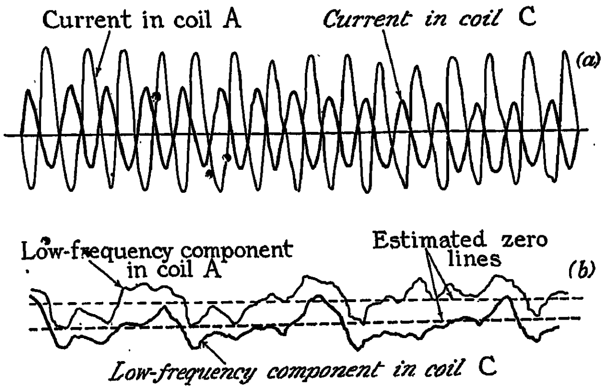

FIG. 13.—Oscillograph records of currents flowing in stator coils with the motor on load at cascade speed.

(a) Portion of film record obtained. NOTE: The scale for the currents in the two coils was made different in order to be able to distinguish them. The currents were actually of the same magnitude.
(b) Low-frequency components of current in stator coils analysed from film record, a portion of which is shown in (a) above. These are in phase with each other.

9 and 5 slots, i.e. a pole-pitch for the 4-pole field, half a pole-pitch, and a quarter pole-pitch. Oscillograph records with the motor operating on load at cascade speed are shown in Fig. 12. The 8-pole flux produced

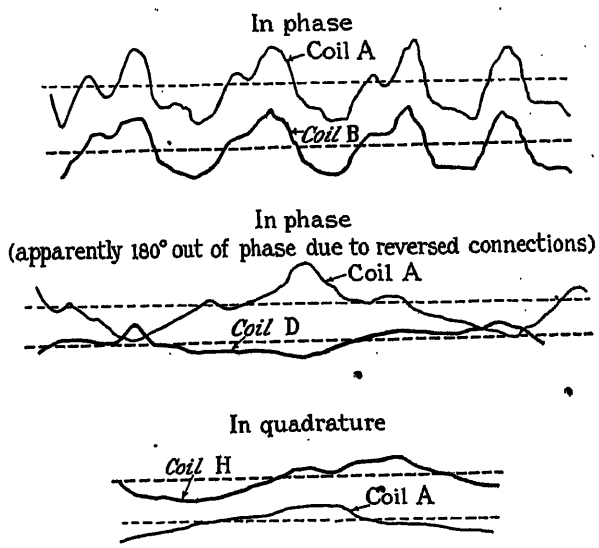

FIG. 14.—Low-frequency component currents in stator coils.

NOTE: (1) The current scales are different in each case for the two currents compared, in order to distinguish the curves.
(2) The time scale is not the same in different cases, due to the film being passed through at different speeds.
(3) The currents were not analysed for coils E, F and G, as the theory was sufficiently well established by the analysis of the currents in coils A, B, C, D and H.

by the stator is rotating relatively to the search coils at a high speed, while the 4-pole flux produced by the rotor cuts the search coils at a low speed. The E.M.F. induced is, therefore, almost entirely due to the 8-pole flux, and this is borne out by the oscillograms which show a sine wave in two cases and only a few ripples in the 18-slot span coil.

Owing to the rotor winding being in semi-enclosed slots, it was not possible to wind search coils on the rotor. Such coils would have shown the compound resultant field, as the two fluxes rotate at the same speed relative to the rotor.

The circle diagram of this machine was obtained both for cascade speed and non-cascade speed. It was found that the no-load losses were practically identical at both speeds. At cascade speed the machine took a much larger magnetizing current than at non-cascade speed, but the power factor was lower and the power consumed the same.

It is probable that the iron losses were slightly higher at cascade speed, but this must have been offset by the reduction in windage at the lower speed.

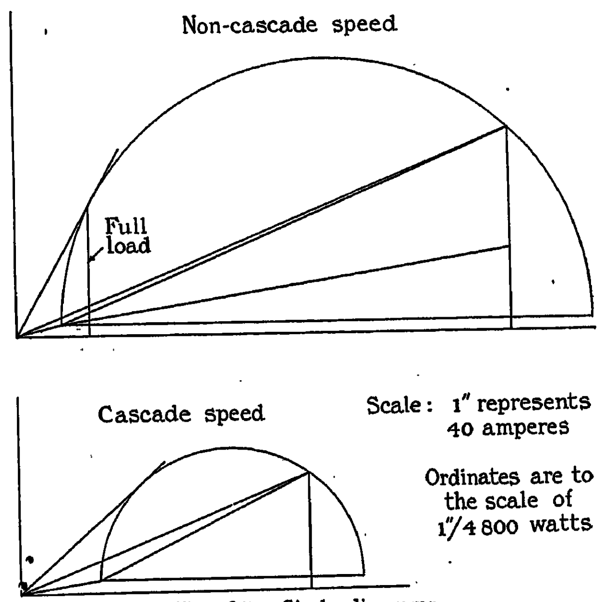

FIG. 15.—Circle diagrams.

A few of the results obtained from the circle diagram and also from load runs are given below. The circle diagram is also reproduced in Fig. 15.

Non-cascade speed (synchronous speed 750 r.p.m.).

No-load current, 9·4 amperes; power factor, 0·23.
No-load losses, 760 watts.
Maximum power factor, 0·88.
Full-load efficiency, 82 per cent.

Cascade speed (synchronous speed 500 r.p.m.).

No-load current, 16·2 amperes; power factor, 0·14.
No-load losses, 830 watts.
Maximum power factor, 0·68.
Full-load efficiency, 73 per cent (approx.).

The experiments were carried out in the Laboratories of Applied Electricity, The University, Liverpool, and the author's thanks are due to the Faculty of Engineering and Professor E. W. Marchant, D.Sc., for per-

mission to publish the results obtained. Thanks are also due to Prof. Marchant and Mr. J. C. Prescott for the assistance and guidance given in the experimental work and in the preparation of the paper.

DISCUSSION ON "ELECTRIC PASSENGER LIFTS." *

WESTERN CENTRE, AT PLYMOUTH, 2 FEBRUARY, 1925.

Mr. T. Hood: The paper appears to deal almost exclusively with lifts operating with direct-current equipments, and I should feel obliged if the author would say what his experience has been in respect to alternating-current equipments for passenger and goods lifts. There are several towns in the West of England, such as Bristol, Cheltenham, Bath and Bournemouth, where public supply is only available from high-frequency single-phase circuits. Can the author say what special characteristics should be observed in single-phase and polyphase motors for lift duty?

Mr. T. Stretton: The author's remarks in regard to the frequent failure of the architect to co-operate with the engineer are timely and to the point. Installations which could undoubtedly be made first-class jobs are being continually spoilt through such lack of early co-operation, and unfortunately it is always the engineer who is blamed for a bad job. No reference is made in the paper to the use of continuous lifts, and I should like to have an expression of opinion from the author as to whether this type of lift would not have been cheaper to install and maintain in many cases where ordinary lifts have been installed. I refer, of course, to installations in buildings of moderate height, say four or five storeys. It may be of interest if I give a description of a novel electric lift installation in Cardiff. A jeweller's strong room is in the basement immediately below his window, and is in the form of a square well. The lid is of the ordinary strong-room door pattern, and is arranged to travel from the top of the strong room to a sufficient height to be out of sight of anyone looking in at the shop window. The jeweller's most valuable stock is arranged on properly designed window shelves which are suspended from the under side of the strong-room lid. At night the whole of this stock is simply lowered into the strong room and the lid locked. In the morning the operation is reversed. There is a great saving of labour and almost perfect security. I agree with the author's contention that long periods of acceleration and deceleration are more pleasant for passengers, but this fact should not be allowed to interfere with the efficiency of any installation. Passengers very soon get accustomed to quick acceleration. This is conclusively proved in the case of colliery winders. I should like to ask the author why more use is not made of flat ropes. The drive is in most cases central and not skew, and I should have thought that the flat rope would have many advantages over the circular rope, including less wear. The author states that with an automatic lift a single passenger obtains complete control over the lift until he has completed his journey, although there may be many passengers waiting at intermediate floors. Surely this

* Paper by Mr. H. Marryat (see vol. 62, p. 325).

is not correct. I am under the impression that each set of buttons on each floor includes a "stop" button so that any waiting passenger can stop the lift.

Mr. W. J. Bache: I have found the energy consumption of lifts to be extremely small, and the bill for energy used is sometimes only a few pence per week. Many of the minor faults that occur could be prevented by frequent and competent inspection, and I consider that lift-users generally do not appreciate the importance of inspecting the mechanism frequently as a means of preventing trouble. Contacts are often too flimsy and should be generously rated. I prefer clapper contacts with carbon blocks to sliding brass or copper contacts. Can the author explain why ropes wear unduly between the sheave and the attachment to the lift gear? Automatic self-closing doors of the Bostwick pattern are needed and I should like to inquire whether there is a satisfactory pattern on the market at a reasonable cost. The need for providing all bearings with renewable bushes should be emphasized. I should be glad if the author would indicate the best method of testing the safety gear of a lift without running undue risk.

Mr. A. C. MacWhirter: Architects are much to blame for not making proper provision for lifts when planning new buildings. They do not provide sufficient space or arrangements for satisfactory lift installation, consequently lift manufacturers are considerably handicapped in their designs. They would be well advised to consult lift experts, who would no doubt be able to show them considerable savings in their constructional and general arrangements. In the past we have looked upon American lift practice as "the last word," entirely on account of their unique requirements in their multi-floor buildings, the lift being (broadly speaking) the only communication from the street to the floors. As a result they have had to develop very high-speed lifts. British manufacturers are, however, now up-to-date with their practice and quite able to improve on their designs to serve our requirements more suitably. Push-button lift control is now giving satisfaction, but, in common with most automatic devices, it requires regular attention if it is to give reliable service. The combination of push button and car switch seems to me the most serviceable and economical kind of controller, as it allows the lift to be controlled by an operator during "rush hours" and by push button during the quieter hours. I should like to know why ball or roller bearings are not more generally used, especially on motors and worm gear shaft, in preference to solid bearings. The starting torque would be much less and consequently the acceleration would be increased. Regarding drum and vee sheave driving, I should like to know what is the difference in the life of the ropes in the two cases. I should imagine that there is bound to be considerable slip on the vee sheave, with resulting increase in wear, as compared with the drum type of driving. Can the author say what is the latest practice in motor windings, i.e. whether series windings are used for assisting starting, and if more than one shunt winding is used for speed regulation? Castor oil seems to be generally used for worm gear lubrication. I have known of cases where this oil has become so gummy that difficulty was experienced in starting the lift after standing overnight—especially in cold weather. I should have thought that a good mineral oil would have been the best form of lubricant for this purpose. The counterweighting of lifts is a very important item, and I believe that the correct practice is to load the counterweight to balance the cage plus 50 per cent of full load. I should like to have the author's views on this important point. On the sheave type of drive I have noticed that certain manufacturers have only two bearings with the load carried externally to the bearings. This practice is, I think, very bad; there should always be an out-board bearing which should be lubricated by means of ring lubricators and not grease cups.

Mr. E. E. Benham: Continuous lifts on the escalator principle have been referred to by one speaker. Lifts of this character for material but not for passengers have been installed in one or two of H.M. ships recently, but it is not possible to give any detailed particulars.

Mr. W. G. Heath: Can the author give any information regarding the self-levelling of lifts at different floors, thus obviating the necessity of footlights and the cage stopping anywhere but at the intended floor?

Mr. C. T. Allan: We have had our Cardiff office 5-passenger lift converted from operator control to automatic, with a resulting much increased service to users of the three floors. Much interesting information has been obtained, such as :—

Distance travelled per day—2·8 miles.
Distance travelled per month—90 miles.
Average trips per day—500.
Passengers—467 per day, 11 300 per month.
Consumption, units—2·3 per mile and 2·73 per passenger-mile.

Percentage of total passengers per floor.

Ground to 1st floor— 6·1 per cent.
Ground to 2nd floor—58·8 per cent.
Ground to 3rd floor—35·1 per cent.

Other figures show that the lift is used almost twice as much going up as coming down. Troubles have been rare, the lift being maintained and inspected monthly by the makers. The lift is illuminated, the light being switched on by means of a spring contact in the floor, operated by the passenger when stepping in.

Mr. H. Marryat (*in reply*): A motor for lift duty must give at least 2½ times full-load torque when starting. For single-phase circuits, therefore, a special type of motor must be employed. There are several suitable machines upon the market, but perhaps the best known are the Bandy motor and the Parkinson motor. These are machines of the commutator type having a shunt characteristic. In both cases the stators are double wound in order to provide means for reversal. In the Bandy motor the shunt characteristic is obtained by means of a shifting brush rocker operating automatically. In the case of the Parkinson motor the brush position is fixed and the effect is obtained by means of a compensating winding and transformer. Polyphase circuits present less difficulty. Slip-ring induction motors give the necessary starting torque. Special windings

providing for two or three speeds must be employed in the case of high-speed lifts. Perhaps the most serious trouble encountered with alternating-current lifts is hum, which becomes intolerable in dwelling houses if special provision is not made to reduce this nuisance to a minimum.

Continuously-running lifts were at one time commonly used both for passengers and for goods. For passenger service they have been abandoned, because if they are run at a speed low enough to be safe they are a great deal too slow for modern ideas of transport, in fact it is quicker to use the stairs. On the other hand, for goods service the idea has been highly developed and is the basis of modern conveyer design.

The description of the jeweller's window lift is extremely interesting. It has been suggested that in areas where window space is of great value the window dressing should be changed in much the same way as described by Mr. Stretton, the new dressing being arranged in the basement and lifted into position, whilst the old dressing—rolled aside for the moment—is then lowered to the basement to be dismantled.

The reasons why flat ropes are not used for passenger-lift work are that the round rope gives a maximum of strength for weight, will lay upon the drum more accurately, will tend to increase its grip upon a traction sheave with increase of load, and will give a longer warning of failure. Apart from these technical reasons it is probable that the cost of a flat rope would be somewhat more than the cost of a circular one.

Mr. Stretton is mistaken in thinking that a stop button is fixed at each floor. That may be done in the case of service lifts, but would never do for a passenger lift because, in a busy office building, no one would get anywhere on account of the continual interruption and reversal of the journey. A stop button is always placed in the car to enable passengers to correct any mistake made in pressing the wrong floor button.

In reply to Mr. Bache, I have not found lift ropes to wear anywhere but where they pass over a sheave. If trouble is found near the anchorage of the ropes to the car or balance-weight, the cause is probably the same as that which produces similar results upon many crane ropes, and is probably associated with too rapid braking or acceleration.

There are several automatic self-closing gates upon the market, but I do not know of one which is entirely satisfactory and at the same time reasonably inexpensive.

The usual way of testing the safety gear is to take a loop in the rope by means of a hemp lashing, which is then cut with a knife. Where the safety gear is controlled by a slack cord it may be brought into action by merely pulling the cord. Governor safety-gear may be readily tested by inserting an adjustable resistance in series with the shunt field of the motor and, when the lift is running, switching in the resistance until the speed increases to the pre-arranged value at which the safety gear is to operate. I entirely agree with all the other remarks made by Mr. Bache.

In reply to the question as to why ball or roller bearings are not more used in lift construction, I would point out that we are dealing with a machine which—because it acts upon a see-saw principle—consumes an absurdly small amount of energy. Energy consumption is a very small part of the running cost, and it is doubtful whether the cost of the massive ball bearings required would be justified. In this connection it must be remembered that lift makers voluntarily sacrifice 50 per cent of efficiency by making the worm-gear self-sustaining. This is a sacrifice of energy cost in order to ensure safety.

With regard to the life of ropes upon drum and sheave drives, if the drum and the sheave are of equal diameter the ropes will last longer on the drum. But this is very seldom the case in practice. Where one finds the drum introduced, it is usually in order that a higher-speed machine may be utilized, and consequently the drum is of smaller diameter than would be necessary for a traction sheave for the same job, and any advantage of drum over sheave as regards rope life is lost on account of the more acute bending of the rope.

The subject of d.c. motor field-windings is too large to deal with in this reply. For ordinary low-speed lifts a series winding is usually added to the shunt field and is automatically cut out when the motor reaches full speed. For higher-speed lifts many varieties of windings are employed.

Castor oil is found to be the best for gear boxes, because it is not easily pressed out from between the faces of the worm and wheel teeth which have to sustain great pressure. If the castor oil gums up it is because an insufficient quantity is employed and consequently the temperature-rise is too much.

The counter-weighting of lifts is dealt with in the paper. The usual practice for new lifts is 40 to 50 per cent of the maximum load plus the weight of the car, but an adjustment should be made after the average load has been ascertained in practice, as the correct balancing to the average load has an important effect upon the energy consumption.

I entirely agree with Mr. MacWhirter in his criticism of the practice of overhanging the driving sheave without an outer bearing. With regard to self-levelling, this has been dealt with in the paper.

The information given by Mr. Allan regarding a particular lift is extremely interesting, and it is very desirable that engineers should collect such information whenever opportunity occurs. It is upon data of this sort, in sufficient quantity, that lift engineers depend when advising as to a suitable lift equipment for a particular building.

DISCUSSION ON "ELECTRICITY IN MINES." *

DISCUSSION AT A JOINT MEETING OF THE WESTERN CENTRE OF THE INSTITUTION, THE SOUTH WALES INSTITUTE OF ENGINEERS, AND THE SOUTH WALES SECTION OF THE ASSOCIATION OF MINING ELECTRICAL ENGINEERS, AT CARDIFF, 12 JUNE, 1925.

Mr. W. O'Connor: Of all the data in the paper perhaps the most apt illustrations of the author's methods are those contained in the last two lantern slides. The first of these showed a site almost untouched in November 1923, and the second the same site with a colliery on its way to full development in the following year. Those who were told that they were wasting the very valuable resources of this country in burning coal at a much greater rate than they should, will derive great benefit from the paper. Many of us are inclined to think that some of the conditions laid down in the paper are utterly unattainable under present-day conditions, but there is much in the paper that we can use for the benefit of the concerns of which we are in charge.

Mr. D. Jenkins: Owing to the growth of our power supply undertakings and of generating stations in general, equalized electric winders have largely become unnecessary, and as a result the modern tendency is to omit the flywheels from Ward-Leonard sets. If my interpretation of it is correct, the present paper confirms this opinion. It is no doubt a step in the right direction, because from the point of view of the winding problem alone equalization brings no advantage. On the contrary, it increases both the capital and running costs of the equipment. Furthermore, as the number of electric winders connected to a system increases, the improving diversity factor will render equalization increasingly unnecessary. It seems likely, in fact, that within a comparatively few years the installation of an Ilgner equipment will become rare. By dispensing with the flywheel, speed variation of the motor-generator set becomes, of course, unnecessary, so that to install synchronous instead of induction driving motors seems a natural step to take. Nevertheless, the author is to be congratulated on being one of the first to break away from orthodox practice in this respect. I have always viewed the Stjernberg coefficient with suspicion. It would be exceedingly imprudent to decide, merely on the value obtained for this coefficient, whether for given conditions a Ward-Leonard or a straight induction-motor winder should be installed. A winder drive is affected by a large number of complex considerations which are not reducible to any mathematical formula. The coefficient in question, for instance, ignores entirely such considerations as those of economy, floor space, ease of control, etc. For these reasons I regret the coefficient has been put forward again. The present tendency is to install a straight induction-motor drive in preference to a Ward-Leonard set, on the ground of simplicity and cheapness. The modern practice of hoisting heavy loads at low speeds instead of light loads at high speeds has extended the field of economical operation of the induction-motor drive. Its great disadvantage as compared with a Ward-Leonard set is its comparative difficulty of economical control. The fact that its power input depends only on the torque and is independent of the speed inevitably means heavy losses during the acceleration period. Further losses take place during the retardation period because regenerative braking is impracticable. The only practicable means at present of reducing the former losses is to use multiple-speed motors or variable-speed gears or one or other of the many special methods of utilizing the slip energy regeneratively. All such means, however, involve complications, and their adequacy for the purpose in question is very doubtful. Has the author had experience with any of them? Judging from my own experience, reverse-current braking on induction-motor drives is by no means easy. The curves in Fig. 7 show that the braking torque producible by any given rotor circuit resistance depends upon the speed. It is difficult, therefore, to ascertain the correct position of the controller for a required braking effect. Furthermore, one cannot tell whether a forward or a backward motion of the controller lever is necessary to give a required variation of the braking torque, because this depends upon whether one is working on the one side or the other of the maximum on the torque curve. The result of these doubts and indecisions is that the winding engineman, for the sake of safety and precision, relies too much upon mechanical braking. Has the author found the same trouble? Of course, reverse-current braking involves a heavy duty on the controller, and it is clear this should be taken into consideration when designing the controller. I suspect that this point is frequently overlooked.

Mr. A. B. Muirhead: The Powell Duffryn Co. are placed in an unique position which admits of centralization of power being carried out to a much greater extent than appears to be practicable in other mining districts, and it is a matter of debate at the present time whether centralization on the same scale could be carried out with the same advantage in other areas. The lower grade of boiler fuel available in many of the coal-mining districts of Great Britain makes the splitting up of power stations desirable if only to reduce the cost of transporting the lower-grade fuel from the various pits to the central point, and the quantity of water to be pumped in many instances renders it desirable that there should be more than one power station available in an emergency. It will be found in many instances that, owing to the facilities available for the generation of power at low costs from these lower-grade fuels which

* Paper by Major E. I. David (see page 521).

will not pay to transport to any market, power can be obtained at sufficiently low cost and at reasonable efficiency with moderate steam pressures and superheat to enable the colliery owner to decide to use either electricity or compressed air underground as may best suit his mining conditions. The example of the Powell Duffryn Co. in these respects may be followed with advantage as far as the physical and economical conditions admit in each area.

Mr. F. Anslow : The author showed a lantern slide of a turbine plant coupled to two generators for supplying power to an electric winder, and remarked that he would not criticize this combination as it had only been in operation for a few months. As a matter of fact, three plants on this principle have been running for nearly 20 years, the only difference being that the generators, instead of being driven through gearing by a turbine, are driven direct by means of a high-speed engine. Indeed, these plants go a step further than those illustrated by the lantern slide, in that they have an additional generator included for the supply of current at a constant voltage, as distinct from the variable voltage of the Ward-Leonard sets. I am sure, therefore, that the author will be interested to know that the plant is in no way experimental, but is rather a revival of what has been done many years ago.

Captain A. C. Sparks : The paper refers more to electricity on the surface of mines than in mines, as the title would lead one to believe. It would be interesting to hear more about the old jockey pulley drive with modern improvements introduced by the author, as mentioned on page 522, unless he refers to the Lenix drive made by Messrs. Sulzer. With regard to the author's remarks on the subject of fan drives, when last in the United States I noticed that in one of the big coalfields it was the general practice to reduce the speed of the fans considerably during the light-load shifts, although it is not generally done in this country. This factor is largely decided by the mine manager, and I suggest might be further considered. In the Illinois coalfield, where the power required for the fan is, generally speaking, less than that required in South Wales, and the total units per ton are only about 1/10th of those required in South Wales, primarily owing to the natural facilities for coal getting, it is found desirable to do this. With reference to compressors, I feel that unless more consideration is given to the efficiency of the mechanical side the saving on the electrical side mentioned by the author may be lost. The low-load losses require to be carefully considered with the type of load experienced at collieries. The author briefly refers to pulverized fuel, stating on page 525 that " where fuels are available which cannot be burnt on any ordinary stokers, pulverizing is a feasible proposition." I doubt the accuracy of this statement without qualification, and do not feel that the subject is one that can be generalized upon at the present time. Whilst some time ago it was generally supposed that the feature of pulverizing was that the poorest fuels could be used commercially, it is interesting to note that the leading power houses using pulverized fuel in the United States are employing fuels having a calorific value about 12 500 B.Th.U. as received, which is by no means a poor class of fuel as we know it. As regards using low-grade fuels, the cost of pulverizing increases materially the lower the grade. I do not know what fuels the author has in mind, but abroad I have seen slurry, the residue from the water used for the washery, containing some 30 per cent moisture and 25 per cent ash, burnt on stokers, and also fuel containing 65 per cent ash. This latter fuel appeared to consist of small veins of coal in pieces of stone. Ignition was assisted in the former case, and combustion in the latter, by gas from coke ovens. The difficulty did not appear to be so much the burning of these fuels as the handling. With regard to winder gearing, I think that the question of using forced lubrication on the gearing, mentioned on page 526, is more a matter of gear design than of the size of the plant. I know one winding equipment with a motor of some 1 500 b.h.p. which has operated satisfactorily for several years without forced lubrication. With regard to the reversing switchgear, the author states on page 528 that apparently the blow-out coils were less effective when current and voltage are considerably out of phase. Power factor has a considerable influence on the breaking capacity of switchgear. With regard to the comparison of an Ilgner against a straight Ward-Leonard system, the author rightly points out that the figures given in Table 4 require adjustment for the difference between the winding schemes under the two cases cited. The figures might be materially changed on this account. A further point is that I believe that the Ilgner set mentioned was installed about 14 years ago, and is compared with a plant which was recently installed and which, I think, has not yet operated upon the coal-winding cycle. In this connection it may be interesting to note the progress in electric winding, and as this conference has had the privilege of visiting one small section of the Powell Duffryn Co.'s undertaking—and they are so associated with this progress—it may not be out of place to mention some of the work of that company, which, thanks to the enterprise of Mr. Hann and his family, is second to none in the efficient use of power, and has done so much to further development in the use of electricity at mines. In 1909 the first electric winding equipment was installed, an a.c. motor being used with direct drive. This type of equipment has limitations with which we are now all familiar. In 1911 an equipment of the Ward-Leonard-Ilgner type was installed, the generators being driven by an induction motor. At this time far less power was available than is the case to-day. In 1918 an a.c. geared winder was installed at a smaller cost than the Ilgner equipment, the power house equipment having materially increased at this time. In 1923 a Ward-Leonard equipment was installed, a synchronous motor being employed for driving the generators. This was of assistance in power factor correction, the need for which became so necessary as the extent of the undertaking increased.

Mr. R. G. Isaacs : I should be much obliged if the author would explain why it is that for pumping motors he uses induction motors almost entirely instead of synchronous motors.

Mr. H. Cotton (*communicated*) : The author's atti-

tude towards synchronous motors of the induction type has been criticized on several occasions, the paper apparently giving the impression that he is not too favourably inclined towards this kind of machine. This attitude may be due to the fact that some engineers have not realized that the induction type and salient-pole type of synchronous motor behave quite differently both during the starting period and during normal running. These differences provide a useful basis for comparison.

Starting.—The synchronous induction motor starts up exactly like an ordinary induction motor, its rotor being of orthodox construction except that it is wound for lower voltages than the rotors of plain induction motors: this has no influence on the starting torque. The exciter may be left in circuit during the whole of the starting period, but except when the slip is very small the pulsating torque produced by it has an average value of zero so that it does not contribute to the starting torque. The exciter is thus only called upon to pull the motor finally into step after the full

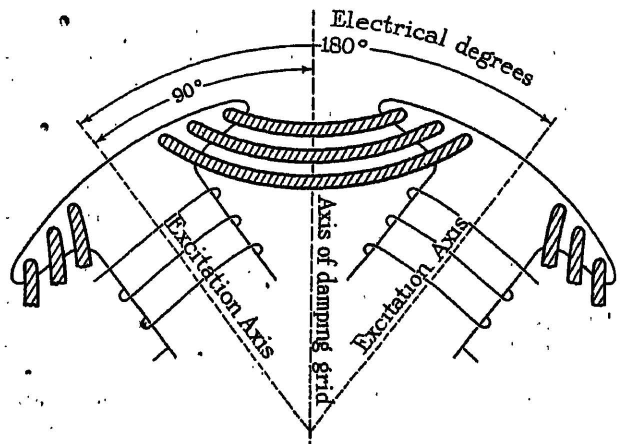

FIG. A.

induction-motor speed has been attained. Because of the above characteristics, the motor can start up against full-load torque, or even $1\frac{1}{2}$ times full-load torque, and can synchronize against these. The salient-pole motor is inherently a motor of low starting torque, and if starting torques comparable with those of the synchronous induction motor are required it is necessary to complicate the motor very considerably. The essential condition for a high starting torque is that the induced rotor currents should set up a rotating magnetic field whose amplitude should be as nearly constant as possible, that is, the field should be circular and not elliptical. This condition is not fulfilled when the motor is started up by the eddy currents induced in solid pole-shoes, or in damping grids of ordinary construction, since the induced currents in these cases are more in the nature of single-phase currents. The field set up by these currents has therefore a small rotating component but has a large alternating component, this latter being responsible for the sudden falling-off in starting torque when half synchronous speed has been attained. Several methods have been adopted to overcome this difficulty but unfortunately they all add to the complication of the machine, and incidentally to the cost. One method is to provide the pole-faces with a complete three-phase bar winding, the air-gap being reduced somewhat so that the motor has ordinary induction-motor starting characteristics. This is perhaps the ideal from the starting point of view, but it must be a very expensive construction, and even if one of the slip-rings is used by both exciting and starting windings the motor will require four slip-rings. The method adopted in the S.G.E. motor described by the author is very interesting, but there appear to be three serious objections to it. First the whole arrangement of the control appears to be unduly complicated, secondly the induced field will have a large alternating component, and thirdly, the damping windings which act in conjunction with the ordinary exciting windings to give the necessary starting torque will not act as dampers at all when the motor is running normally. The second objection follows from the essentially very different characteristics of the pole-face winding and exciting winding, even when the latter has its two halves connected in parallel. The motor must therefore suffer an appreciable drop in starting

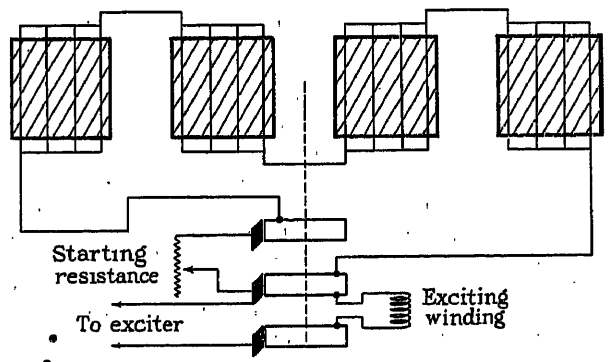

FIG. B.

torque when half speed is attained; and it will have a tendency to creep too slowly past this point, although probably this is not noticeable when driving a compressor, owing to the easy starting characteristics of this kind of load. The third objection is rather peculiar and it appears to have been overlooked previously. In order that a rotating field may be set up, the axis of the damping winding must be displaced 90 electrical degrees from the axis of the exciting winding, this latter acting as one phase, as shown in Fig. A. When the motor is running normally, the damper, to be effective, must be arranged with the centre of each grid coincident with the polar axis, whereas in the S.G.E. motor the grids are each 90° from the polar axis. In this position they will have practically no E.M.F. induced in them in the event of phase-swinging taking place during normal operation, and therefore as dampers they will be practically inoperative. The method of obtaining the necessary rotating field with the least complication is probably the two-phase arrangement shown in Fig. B. Here the orthodox damping grids

are joined together across the interpolar gaps, first on one side then on the other, so that the outside bars of the grids along with the connecting strips form a second phase displaced 90° from the polar axes. This phase is brought to two slip-rings, one of which is shared by the exciting windings, so that altogether only three rings are required as in the S.G.E. motor. Now in order that the two phases of this starting winding may have characteristics as nearly equal as possible it is necessary to have a large ratio of pole arc to pole pitch, and also to employ a narrow air-gap. But with such a construction the excessive magnetic leakage at the pole-tips and the effect of armature reaction, which would be large owing to the high value of the ratio (armature strength)/(field strength) occasioned by the use of a narrow gap, would practically wipe out the field set up by the second phase of the starting winding. This difficulty is overcome by employing a narrow gap at the pole face and by inserting non-magnetic liners between the pole cores and yoke. The total air-gap, from the point of view of the main field, is therefore a long one and the armature is magnetically weak in comparison with the field.

Running.—Although the synchronous induction motor shows up to advantage as regards starting conditions, the reverse is the case as regards normal running. Owing to the narrow air-gap of the induction type machine, it has a relatively strong armature which tends to produce instability if the load is at all fluctuating. On the other hand the very long air-gap of the salient-pole motor necessitates a magnetically strong field, and this renders the running of the motor very stable even with violently fluctuating loads. No better illustration of the stability of the salient-pole motor could be found than that afforded by the synchronous-motor-driven converter sets for the main winders at Llantrisant. In order to improve the operation of the synchronous induction motor in this respect it is usual to employ an air-gap somewhat longer than that used for a plain induction motor of the same size. Another method is to use an automatic regulator which adjusts the excitation to suit the magnitude of the load. Such a device should give a better utilization of the motor on fluctuating loads, since its use enables a smaller motor to be employed than would be possible if the motor ran with constant excitation.

General.—Except for machines with a small number of poles, say up to 6, a greater output for a given frame can be obtained with a salient-pole motor than with a synchronous induction motor, because the field ampere-turns do not become a limiting feature, and advantage can be taken of this to make use of an air-gap which is longer than that required for mechanical reasons alone. The induction-type machine is essentially a high-speed machine, whereas the salient-pole construction is more suited to medium and low speeds. On salient-pole machines the short-circuited winding chokes down the flux entering the poles at starting, thereby reducing the voltage across the slip-rings. This permits of a large number of turns per bobbin of the exciting winding, so that a standard excitation voltage can be used. When starting the induction type of motor the full voltage is switched on to the stator, and in consequence the field (rotor) turns must be kept low in order to prevent a very high voltage being set up across the slip-rings. In a plain induction motor of large size this voltage may be as high as 2 000 or 3 000 volts, obviously much too high for a circuit containing a small d.c. exciter, whether the exciter is left permanently excited or whether it is switched in by means of a manually operated change-over switch. This difference in the excitation voltage of the two types is very clearly illustrated by the following figures. The salient-pole synchronous motors of the Ward-Leonard converter sets at Llantrisant each have a capacity of 1 750 kVA, their excitation being 225 amperes at 65 volts. The fans at the same colliery are driven by synchronous induction motors each of 500 kVA capacity, the excitation for these being 370 amperes at 15–27·5 volts. In consequence of the low excitation voltage, the exciters of synchronous induction motors have to be built with very long commutators.

Although the author mentioned the use of turbo-speed compressors for long-distance transmission of compressed air, he did not refer to the driving of such compressors by electric motors. Presumably the compressors in use at present are all driven by steam turbines, as indicated on one of the lantern slides. What, in the author's opinion, is the most suitable type of electric motor for such a drive? The choice of motor appears to be the turbo-type synchronous motor, i.e. the motor having the same essential constructional features as the turbo-alternator, and the plain induction motor. The turbo-speed induction motor can, of course, be run as a synchronous induction motor, but it is more unstable when synchronized than the synchronous induction motor running at lower speeds, and would therefore probably not be considered. The turbo-speed induction motor has exceptionally good operating characteristics, its full-load power factor is high, and there is thus no necessity to employ a synchronous motor unless power-factor correction is a necessity. The cost of these motors is considerably less than that of synchronous motors of the turbo type. Possibly for very large outputs the synchronous motor would be preferable.

Major W. Roberts (*communicated*): About 12 months ago the author told me that his practice was to start motors up to 50 h.p. in size by switching them straight on the line. I notice that in a year his ideas on this subject, like many others, have progressed and he now talks of switching 150-h.p. motors straight on the line. In this respect I think he deals with bigger figures than anyone else, and the average colliery or supply undertaking would strongly object to this procedure. I take it that in his case it is only possible due to the size of his plant and the other apparatus connected to the lines. Can the author give any information as to the size of machine that can be started in this manner without harm to the remainder of the plant, as a percentage of the total generating plant and the load connected? Even with the special type of winding to which he refers, I take it that the current on starting is three or four times the normal

full-load current, and as this presumably means that his overload releases are inoperative during the starting process, does he not think it a disadvantage to have machines of such large size coupled directly to his supply without any protecting device as they (presumably) are with a two-position starter? In describing one of the lantern slides the author gives 23 or 24 per cent as the starting torque of a compressor with an unloading device. Can he state what this figure would be for ordinary reciprocating compressors without unloading device? He mentioned, I think, that on one job the starting current was approximately equal to normal full-load current, but this figure appears to me to be somewhat on the low side, and I shall be glad to know if it is a figure that he has consistently found in practice.

Major E. I. David (*in reply*): Mr. Jenkins is suspicious of the Stjernberg coefficient. As I have previously stated, it must be used with circumspection. It is useful as a first approximation for eliminating the extremes. Nothing but a complete examination, by experienced engineers, of all the complex factors can finally settle the best type for each particular purpose. Reverse-current braking is far simpler than would appear from the curves in Fig. 7. To attain creeping speed, the resistance in the controller is such that a movement away from the central position of the lever through a limited range increases the braking torque at all speeds. In the large a.c. winders described (see Fig. 6) the mechanical brakes are only used to effect the final braking and to hold the drum stationary; all main deceleration and weight-lowering is done by reverse current. The heating effect of this must be calculated and the controller and the motor rotor designed accordingly.

Mr. Muirhead rightly refers to some of the factors which have to be considered in the power supply for a group of collieries. In the case mentioned there are six main power stations all interlinked electrically, utilizing gas and low-pressure, high-pressure and extra-high-pressure steam. Duff coal is used almost exclusively for steam generation.

Mr. Anslow's reference to the 20-year-old steam-driven Ward-Leonard sets is most interesting and gives rise to the question: Why have more plants of this type not been installed?

In reply to Captain Sparks, the drives referred to are Lenix drives (see also page 565). I would refer this speaker to the figures given on page 524 for the light-load losses in the high-speed vertical-type compressors. The mechanical efficiency of these machines is exceptionally high. The fuels I refer to as difficult to burn on ordinary stokers are low-volatile washery slurries and froth flotation coals, both already very fine and easily pulverized and of high calorific value. Certain gear-makers do not insist on forced lubrication, whilst others, using similar tooth pressures, do. I prefer to be safe and fit sprays in all cases. Captain Sparks may be interested to know that the old direct-coupled 1909 winder motor with a new drum is still doing 100 per cent overload every day in a new pit. The power units available in 1911 were much smaller and equalization was necessary. A 2 500-h.p. winder now bears the same relation to the power units as a 250-h.p. haulage did then.

In connection with Mr. Isaacs's remarks, I would refer him to page 522.

Mr. Cotton's valuable contribution clearly describes the relative merits of the salient-pole and synchronous induction-type synchronous motors. His conclusions agree with mine, namely, that for low-starting-torque low-speed high-efficiency drives such as compressors, the salient-pole machine is preferable and usually cheaper; and that for high-speed high-starting-torque drives with slight overloads such as ventilating fans the synchronous induction motor is preferable. High efficiency is essential, and the synchronous induction motor can be designed for efficiencies nearly as high as those of salient-pole machines for speeds of 600 r.p.m. upwards. For large high-speed motor-generator sets salient-pole machines are cheaper, more stable, more robust and slightly more efficient, whilst their starting torque is ample and their excitation voltage more reasonable. Provided high efficiency can be obtained, I prefer for turbo-compressor drives a plain induction motor, because of its stability and also because the load variations are so extreme that it would be difficult to prevent violent power-factor fluctuation in a salient-pole or synchronous induction motor. The speed of most turbo-compressors of 7 500 to 15 000 cubic feet per minute capacity is from 4 000 to 6 000 r.p.m. Gearing is therefore necessary and a normal machine of 600 to 1 000 r.p.m. is cheaper and more efficient than a machine of the turbo type. Speed variation of 10 to 15 per cent would be a great advantage.

In reply to Major Roberts, switching a 150-h.p. Boucherot-type motor on the line produces a kick of 3 to 4 times full-load current, falling rapidly to $1\frac{1}{2}$ times, but this is small compared with the starting current of a 1 600-h.p. a.c. winder motor. The two overload trips have oil dash-pot time-lags and are set for 75 per cent overload, but there is an instantaneous earth-leakage trip. Induction-motor-driven compressors up to a capacity of 3 000 cubic feet per minute are frequently started up without unloading against full receiver pressure and, when cold, take up to 150 per cent of full-load current, but it is preferable to use the unloading device.

DISCUSSION ON "THE DRIVE OF POWER STATION AUXILIARIES."*

WESTERN CENTRE, AT CARDIFF, 2 MARCH, 1925.

Mr. J. W. Burr: Years ago we did not worry very much about our auxiliaries. If they failed it simply meant running the engine to atmosphere and coupling up an extra boiler. To-day, with turbine units, the failure of any part of the auxiliary plant entails shutting down quickly. Our auxiliaries, therefore, must be reliable, as continuity of supply is essential. The authors state that half an hour's interruption may be attended with disorganization at the works. In my district a much shorter interruption is sufficient to cause great disorganization at the works and collieries, particularly the latter. The importance of the duplication of auxiliaries depends, in my view, upon the number of sets running at one time. For example, if four sets were running it would, obviously, not be so necessary to duplicate the auxiliaries as in the event of the load being taken by one set. Referring to the boiler feed-pumps, I prefer to drive half by steam and half by electricity, and I suggest that if certain of the auxiliaries were driven by d.c. motors in connection with a battery it would not be necessary to install a house set, as suggested by the author. As regards injectors, I think it is common practice to fit these in duplicate, each dealing with 60 per cent of the steam at maximum load.

Mr. F. H. Corson: I should like to associate myself with the view expressed by Mr. Burr as to the outstanding importance of reliability in public electricity supply, even, if necessary, at some sacrifice of cheapness. Economy of generation is governed principally by the main generating sets, but reliability is perhaps more closely dependent upon the arrangement and operation of their auxiliary machinery. I have often been accused of unduly stressing the importance of continuity of supply, and it may be of some interest to mention a few only of the results of a shut-down some 12 months ago, the actual duration of which was only 3 minutes. The machinery of a flour mill was stopped for about 3 hours, a week's output at an artificial silk factory was spoilt, and a charge of ice at an ice factory was lost because a man had such confidence in our reliability as to leave his plant running unattended. At a chemical works some delicate operations were interrupted and possibly ruined altogether, and similar results occurred at a milk sterilizing and pasteurizing depot. I am therefore very glad that the authors have made this the keynote of their paper. I have recently had to consider the question of effective stand-by provision to auxiliary machinery, and have approached it from two distinct points of view: first that of the failure of an important auxiliary, as, for example, a circulating pump the repair of which may take some time, and where the running economy of the stand-by provision must be equal to that of the machinery it replaces; and secondly that of a complete shut-down where running economy is of no importance, and where the simplest and quickest means of recovery must be provided, regardless altogether of its economy of performance. In my opinion the authors acted wisely in confining themselves to a sort of abstract analysis in their investigation of the operation of auxiliaries, and in refraining from making any specific recommendations.

Mr. J. E. Teasdel: It certainly does seem strange to talk at this date about the necessity for a continuous supply. I thought it was generally agreed that this was of paramount importance and overshadowed all questions of cost. There may, however, be extremes in the matter of duplicated auxiliaries, etc. I have known a case in which every engine had two steam pipes to a breeches pipe. After the plant had been running for 20 years the coverings began to fall off the duplicates and they were sold for scrap as they had never been called into use. It would appear to be more necessary to duplicate mains rather than steam pipes, because in these days there is probably more trouble arising outside the station than inside.

Mr. A. J. Newman: I should like to endorse all that Mr. Burr and other speakers have said as to the paramount importance of reliability. Take the case of a flour mill deriving its power from a local supply undertaking. A variation of frequency even may upset their mill operations for an hour or more and interfere considerably with their output. There is also the case of chemical works, to which reference has already been made. It has been our modern practice to install steam ejectors in duplicate for air-extraction purposes. We have not, however, yet reached the stage of having a stand-by for the circulating-pump system, but it is at the present time receiving my serious consideration. I am rather in favour of letting a turbine float on the same shaft as the motor, with an automatic change-over device. I should like to know what the authors think of such an arrangement. With regard to the extraction pump, our practice is to use three-phase alternating current taken from the main busbars for our engine room auxiliary supply and to have d.c. auxiliaries for boiler-house purposes, chiefly because of the desirability of having speed regulation in the latter case. The damage caused by a large turbine going to atmosphere should be avoided at all costs. There are occasions, however, when one may be obliged to go to extreme measures. One of these occasions actually occurred at our generating station. We had a 4 000-kW set running on atmosphere for considerable periods to carry our load over the Christmas peak. As to auxiliaries in the boiler house, our practice is to have steam feed-pumps. We use turbines for this purpose, chiefly because they take the form of feed-water heaters. They are close to the

* Paper by Messrs. L. Breach and H. Midgley (see vol. 61, p. 829, and vol. 62, p. 243).

hotwells and are quite satisfactory and reliable appliances.

Mr. O. S. Hosgood: The list of alternative schemes given in the paper is very useful. A special d.c. generator on the end of the main turbo-alternator shaft would, in my opinion, be a danger. If the alternator set is shut down due to a breakdown, then the auxiliary d.c. set would of course be useless. It is wiser to have the auxiliaries away from the main shaft and have an independent drive. As to having a d.c. plant for the boiler-house auxiliaries, should the d.c. plant break down one must have an alternative scheme to get the auxiliaries going again, because the boiler house is of great importance. Then there is the question of feed pumps in the boiler house. I quite agree with Mr. Burr that electrically-driven pumps should be duplicated.

Mr. P. J. Plevin: I believe that in one American station each of the four or five units it contains is provided with its own house set. These house sets generate current for driving auxiliaries. Each is fitted with a jet condenser, the cooling water for which is the condensate from the main condensers, which have a vacuum of about 29 in., the temperature of the condensate being about 80° F. The vacuum in the jet condenser is, I believe, about 25 in., and the temperature of the water extracted is about 130° F. The water extracted (which includes the condensed steam from the house turbine) is therefore passed into the economizer above the temperature at which condensation takes place on the tubes. Each main and house set is an independent unit. The system has the objection that if the house set breaks down the main set is shut down also. Another objection is that fluctuation in load on the main set means a corresponding variation in the quantity and temperature of the cooling water supply to the condenser of the house turbine, and therefore a variation in the supply of power to auxiliaries. The scheme, however, impressed me as being simple, and I should be glad to have any details of its performance which the authors can supply. The question of reliability has been stressed, quite rightly, by every speaker in the discussion. In earlier days not sufficient attention was paid to matters such as motor control-gear. Very often cheap designs were accepted that were suited only to ordinary commercial work, without consideration as to their relationship to the complete set in respect of immunity from breakdown. Such was also the case with regard to auxiliary turbines. When the turbine drive for auxiliaries first came into favour, many cheap foreign machines of quite unsuitable design were used. In many cases due attention was not paid to the steam connections. It was thought that all that was necessary was simply to take a branch from the main steam pipe to the turbine, and such factors as drainage and provision for expansion were frequently ignored. This is probably one reason why the steam turbine for auxiliary drives fell into discredit. There is one other matter which should be borne in mind, and to which I do not think the authors have alluded. I refer to the layout of auxiliary plant. In older layouts especially, auxiliaries were frequently placed in any position which provided floor space, entirely without regard to accessibility for inspection and overhauling and to the fact that their satisfactory performance is just as vital as that of the main sets. This, of course, is wrong, and in my opinion the proper location and installation of auxiliaries is just as important as that of the main plant.

Mr. R. Roper: We have recently installed a house turbine on similar lines to that mentioned by Mr. Plevin. This unit is complete with turbine, alternator and jet condenser. The condensate from the main units is utilized as cooling water for the jet condenser on this small house turbine. The water from this jet condenser is delivered to hotwells in the boiler house, and from thence pumped into head tanks. The exhaust steam from the head pumps and the feed-pumps still further heats the head tanks, and the temperatures can be taken as 150° F. for the hotwell and 200° F.–220° F. for the head tanks. This temperature can be varied by adjusting the load on the house set by means of change-over switches on the duplicate auxiliary busbars. The efficiency of this house turbine is not of such prime importance as the greatest reliability of service. With regard to our circulating water, we have a large circulating pump of 530 h.p. delivering 18 500 gallons per minute into one common header pipe, and from this pipe we take a supply of circulating water for the various condensers. I much prefer steam-driven to electrically-driven boiler feed-pumps. The exhaust steam from the steam-driven feed-pump can be passed through evaporators, and by so doing we are able to obtain a large percentage of supplementary feed for our boilers. This method is, I think, quite as economical as the electrically-driven feed-pump; in addition, should any trouble be experienced on main generating units the steam pump can always be relied on to feed the boilers. The house turbine runs at 5 000 r.p.m., and this is reduced through gearing to the generator which runs at 500 r.p.m. We are also doing without economizers on our new boiler plant, using air heaters instead.

Mr. W. Holley: The moral to be drawn from both paper and discussion appears to be that we need better auxiliaries. Every operating engineer knows that some of his plant rarely breaks down and that some is more troublesome. If all were as good as the best there would be very few breakdowns. When trouble occurs it is nearly always from some small cause such as a contact too small for its work or a brush difficult to adjust and therefore to keep in order. I suggest that manufacturers should look more into these details—I am sure every operating engineer would gladly assist them. Auxiliary plant is too often installed in awkward positions and consequently is not cleaned and properly examined because of the difficulty of getting all round it.

Mr. R. Hodge: Referring to Mr. Holley's remarks as to the class of apparatus supplied for power station auxiliary control in the shape of contacts, etc., and speaking as a representative of a manufacturing firm, I should like to say that it is the manufacturer's endeavour at all times to provide apparatus of such a quality as will ensure continuity of supply. In connection with the size of contacts, etc., it must always be borne in mind that the financial aspect more often than not enters into this point. If the buyer is prepared to pay a reasonable price he can always be assured

that reputable manufacturers will supply him with an article in which the contacts and other wearing parts are of ample capacity and dimensions to withstand the conditions of service. The question of buying a cheap, if not the cheapest, type of control gear for use in conjunction with the control of power station auxiliaries is very much to be deprecated, especially when one realizes that the cheap control gear may form the one weak link in the chain of continuity of supply.

Mr. H. Wilson: We in the Post Office Engineering Department cordially appreciate, and are ready to applaud, every effort made by power station engineers to ensure that we shall have absolute continuity of service in all circumstances. In practically every telephone exchange in the country we provide duplicate power plant to guard against a failure in the public supply, and at the moment we are installing an 80-h.p. oil engine in a neighbouring town as a stand-by against such a failure. We are naturally desirous that, in general, any duplicate plant necessary should be provided in the power stations and not in Post Offices.

Mr. T. Stretton: This is the day of interlinking of power stations. I assume that we are dealing chiefly with new power stations, and there are very few power station sites in this country where an alternative supply is not available. Every effort should, I think, be made to learn whether an alternative supply is available, and the auxiliaries arranged accordingly. Mr. Wilson mentioned that oil engines were being installed as a stand-by. In a recent lecture before the South Wales Institute of Engineers, Mr. Clark, the consulting engineer to the municipalities of Johannesburg and Pretoria, described a new power station at Pretoria and mentioned that the stand-by plant which he had installed was a petrol engine and generator.

Mr. C. T. Allan: Mr. Plevin has called attention to one of the most important points, namely, reliability. Cases of failure are sometimes due to inadequate protective gear on the switchgear controlling the auxiliary. Sometimes this is too complicated, and what is always needed is simplicity to reduce delay after stoppage.

Mr. T. H. Wood: I think that the authors pass too lightly over the question of the most efficient drive. During this discussion at least two central-station engineers have advocated turbine-driven feed-pumps. I take it that they prefer this type of drive because reliability is of paramount importance in feeding the boilers. This being so, I think that the most serviceable drive would be the one described by Mr. Newman, which incorporates the alternative motor or turbine drive. The normal drive in this case is the steam turbine, because, provided the exhaust steam can be utilized in heating the feed water, this is the most efficient, giving an overall efficiency of about 90 per cent. On the other hand, in the case of the electric drive the efficiency taken over the same range, that is, from steam supplied at the main generator to the power given out at the auxiliary coupling, would only be about 20 per cent. Of course this difference in efficiency is accounted for by the fact that in the first case the whole of the useful and latent heat in the steam is utilized, partly in pumping the water and partly in heating the feed water, whereas in the second case the latent heat is lost, being rejected into the condenser cooling water in the process of converting the steam into electrical units in the main generator.

Mr. W. Nairn: On page 830 (vol. 61) the authors state: "Unless the flow of circulating water through the condenser tubes is due, in whole or in part, to gravity (a highly desirable state of affairs which can rarely be obtained except in hilly countries), it is evident that a stoppage of the circulating water pump will mean a stoppage of the flow of circulating water." Electrical engineers are often criticized for not making more use of water power for generating electricity, and the authors' comment is a reply to such criticism, as the fact is that not a station of any size in this country has been able to command sufficient water power to get a gravity flow for condensing purposes. If such a supply could be obtained either for gravity circulation or for driving the station auxiliaries it would be a godsend to station engineers.

[The authors' replies to the earlier discussions on the paper (see vol. 61, p. 861, and vol. 62, p. 246) cover the points raised in this discussion.]

FUSES AND FUSIBLE CUT-OUTS.*

By P. G. ASHLEY, B.Sc.(Eng.), Student.

(ABSTRACT *of paper read before* NORTH-EASTERN STUDENTS' SECTION, *20th February,* 1925.)

SUMMARY.

The paper briefly reviews the history of the development of fusible cut-outs, and proceeds to discuss in turn the various factors affecting the design and behaviour of wire and plate fuses in air.

The main features of fuse wires in oil are considered and also how their design and behaviour compare with those of fuses in air.

Various types of enclosed and semi-enclosed cut-outs are described, as well as oil-immersed switch-fuses. The theoretical aspect of the mechanism of fusing is summarized in Appendix 1, and the present position as to standardization in Appendix 2.

INTRODUCTION.

In the early days of electricity supply the dangers of short-circuits were not fully realized, and if the station operator could not open his knife switches in time a considerable part of the mains had to be replaced. The idea was conceived of reducing the section of the conductor in one part of the circuit so as to cheapen replacement and reduce the destructive effects of a short-circuit. As the benefits of this practice were realized, improvements were effected in the amount of conductor to be replaced and the means of replacing it, and the fusible cut-out as we know it to-day began to take form.

HISTORICAL.

In 1879 the late Prof. S. P. Thompson invented a cut-out consisting of two iron wires connected by a ball of lead. Under abnormal conditions the lead melted and the wires flew apart. In 1883 Boys and Cunyngham patented a safety fuse with springs; and Kelvin's fuse, which consisted of two pieces of springy copper soldered together by means of a low-melting-point alloy, was produced in 1884. Cockburn brought out his weighted fuse in 1887, and other special forms such as cartridge and Edison plug fuses soon followed. In those days resinous wood was frequently used for the bases, and as a result of these bases catching fire the fuses were often in disrepute. The risk of fire, although not yet entirely eliminated, is to-day considerably reduced by the use of porcelain, slate, and other non-inflammable insulating materials.

DEFINITIONS.

The following are the most important definitions to be noted in connection with the subject of fuses:—

"Cut-out." A device for protecting circuits or apparatus from overload by means of the fusion of a specially designed part.

"Fuse link." That part of the cut-out which is designed to open the circuit by fusing or melting.

"Protected cut-out." A cut-out in which provision is made for protecting the operator from any dangerous effects of operation.

"Rated carrying current." The maximum current the apparatus will carry under prescribed conditions.

"Fusing current." The actual current at which the metallic circuit is broken.

"Minimum fusing current." The minimum current which will, under prescribed conditions, cause the fuse link to melt.

"Fusing factor." The ratio of minimum fusing current to rated carrying current.

MINIMUM FUSING CURRENT.

One of the most important characteristics of a fuse link is its minimum fusing current, which is closely associated with the rated carrying current. Such terms as "normal fusing current" are confusing, and it is better to use the word "minimum" or else to refer to the time of fusing at a definite current value.

The two accepted methods of determining the minimum fusing current are (1) by plotting a curve of fusing current against time and (2) by steadily increasing the current until the fuse melts. In the former case the full current is allowed to flow through the fuse and the time of fusing is noted; whilst in the latter case the fuse is allowed to attain a steady temperature before the next increment of current is applied. Method (1) is the quicker and simpler of the two and the one most commonly employed.

At supply frequencies it is immaterial whether the fuse link is tested with alternating or direct current, provided that only commercial accuracy is required. Tests by the author show definitely, however, that the minimum fusing current with alternating current is lower than with direct current.

MECHANISM OF FUSING.

Fundamentally, while $0 \cdot 24\ I^2R$ calories are being generated each second in the fuse link, dissipation is taking place by conduction, convection and radiation. Neglecting deterioration, any current at which the heat dissipated is equal to the heat generated is a safe continuous rating for the fuse link. It is almost impossible to determine the safe rating theoretically, owing to the difficulty of determining the loss due to the factors of dissipation. Appendix 1 shows the development of various formulæ for determining the minimum fusing current. These formulæ throw interesting light on the mathematical side of the question, but

* A Students' Premium was awarded by the Council for this paper, and it is the practice of the Council in such cases to publish the paper, in full or in abstract, in the *Journal*.

in practice a judicious compromise between theoretical formulæ and reliable test-figures will usually give the required information.

Fuses in Air.

Most of the original investigations on fuse links in air were carried out by the late Sir William Preece. Improvements on his formula have been dealt with by Schwartz and James,* and their paper remains almost a standard work of reference.

Factors Affecting Fusing Current.

The chief factors concerned in determining the fusing current of a fuse link are :—

(1) Diameter of wire, or breadth and thickness of a plate fuse.
(2) Material.
(3) Length of fuse and mass of terminals.
(4) Environment and position.
(5) Time of current-flow.
(6) Whether fuse is in tension or not.

Diameter of Wire.—Assuming all other factors to be fixed, Preece gives $I = ad^{1 \cdot 5}$, where I is the minimum fusing current, d is the diameter of the wire, and a is a constant having the following values when d is expressed in millimetres : Tin, 12·8 ; lead, 10·8 ; copper, 80. Table 1 is calculated from this formula.

Table 1.

Nearest S.W.G. for Given Minimum Fusing Current.

Current	Tin	Lead	Copper
amps.	S.W.G.	S.W.G.	S.W.G.
1	37	35	47
2	31	30	43
3	28	27	41
5	25	23	38
10	21	20	33
15	19	18	30
20	17	17	28
25	16	15	26
30	15	14	25
40	14	13	23
50	13	—	21
60	—	—	20
80	—	—	19
100	—	—	18
160	—	—	16
200	—	—	15

Schwartz and James give the following modifications of Preece's formula :—

When fusing current lies between 1 and 10 amps.

$$I = K_1 d^{1 \cdot 195}$$

When fusing current lies between 10 and 100 amps.

$$I = K_2 d^{1 \cdot 403}$$

* *Journal I.E.E.*, 1905, vol. 35, p. 364.

Table 2 shows how these formulæ compare with Preece's formula.

Table 2.

Comparison of Indices and Constants for Formula of Preece and of Schwartz and James Formulæ.

Material	Range of fusing current, amps.	Schwartz and James		Preece	
		Index	Constant	Index	Constant
Copper	1 to 10	1·195	52·4	1·5	80
	10 to 100	1·403	69·9		
Tin	1 to 10	1·195	10·8	1·5	12·8
	10 to 100	1·403	11·5		

Material.—With tin and lead, owing to their high resistivity compared with that of copper and silver, the size of wire required to carry a given current is greater. This reduces the safety, as a greater amount of metal has to be volatilized when the fuse blows. Aluminium and zinc, although almost non-arcing metals, have the disadvantage of being mechanically weak. A peculiar disadvantage of aluminium is that when the wire is carrying load a skin of oxide or carbonate forms which is sufficiently tough to retain the molten core of the metal. This phenomenon is associated to a lesser degree with tin and lead wires. It was first observed by Cockburn in 1887, and that was why he weighted his wires. The oxide-skin effect is not so noticeable with large wires, as the formation of the skin prevents further oxidation or carbonization. It is probable that the thickness of the skin is constant for all sizes of wire, and therefore has less effect on the larger diameters. Copper is the most common metal used for fuse wires owing to its high conductivity and comparatively low watt loss ; it is fairly "clean" in fusing, and is mechanically strong, cheap, and easily obtained.

Three special forms of fuse links have been placed on the market within recent years, viz. bi-metal fuse wire, the "Aeroflex" fuse element, and the "Zenal" fuse element. All of these are designed on substantially the same principle, i.e. they consist of a low-melting-point metal of comparatively low electrical conductivity in parallel with a metal of high conductivity and higher melting point. On overload the alloy melts fairly slowly, is released, and falls away from the fuse link, leaving the copper alone in circuit. The section of the copper is so proportioned that it will not alone carry the increased current, and the overload is therefore cut off by the copper. The general effect of this principle is that the fuse link can be run at a current value very near to its minimum fusing current, the generated heat being mainly dissipated by the low-melting-point alloy. When the alloy has fallen away, however, the actual work of opening the circuit is carried out cleanly and quietly by the copper.

Length of fuse link.—As shown in Appendix 1, in developing the Preece formula the length of fuse link does not enter into the theoretical determination of

the minimum fusing current. Actually, the effect of this factor is closely associated with the mass of the terminals. To make a true comparison between the minimum fusing current of a long length and of a short length of wire the relation between the length of wire and the mass of the terminals should be kept constant. This condition is practically impossible to obtain. If the mass of the terminals is kept constant the minimum fusing current is proportional to the reciprocal of the length. So far as a short-circuit is concerned, it is only necessary to make the distance between the terminals such that an arc cannot be maintained when the cut-out is subjected to the worst conditions which it will have to encounter.

Environment and position.—Environment plays a large part in deciding the minimum fusing current and therefore the rated carrying current of the fuse link. Types of cut-outs range from open, in which the fuse link is quite bare with a large volume of air round it, to totally enclosed cartridges in which the fuse link is contained in a closed tube packed with some form of insulating powder. The difference caused by these extreme conditions will be appreciated and it will be seen that no theoretical estimate can be made of this effect.

Tension.—The object of employing spring tension is to give the cut-out a higher breaking capacity; the reduction in minimum fusing current which also results is very often undesirable. It is unlikely that Ferranti in his early oil fuse adopted spring tension to increase the breaking capacity, as it was little understood in those days: it is more probable that he found it a convenient means of preventing flash-over between the terminals.

Plate Fuses.

Plate fuses allow more scope in design than wire fuses, owing to the fact that considerable variations in minimum fusing current can be obtained by suitably proportioning the breadth and thickness of the plate. In addition, for the same volume of metal a plate fuse will carry much more current than a wire fuse, owing to the larger cooling surface.

Watt Loss and Fusing Factor.

The watt loss at normal load depends upon the fusing factor, i.e. the ratio of minimum fusing current to normal load, or rated carrying current. A fusing factor of 2 is frequently asked for by supply undertakings, but it is very doubtful whether this factor is suitable. A factor of 3 is preferable, as this considerably reduces troubles due to deterioration as a result of oxidation. A large fusing factor means a high overload setting, but low watt loss and a minimum of oxidation troubles. A small fusing factor gives definite action for light overloads, but is liable to give trouble due to heating.

Fuse Links in Oil.

In the opinion of Schwartz and James no fuse wire should be used in actual contact with oil. Despite this opinion, oil-immersed fuses are giving satisfactory service in all parts of the country. The same development has taken place as with circuit breakers: the oil-immersed circuit breaker is the natural outcome of the need for apparatus capable of breaking large currents at high voltages, and the oil-immersed fuse is the outcome of the same need.

The previous remarks regarding fuse links in air apply equally to fuse links in oil. Copper, tin, lead and bi-metal fuse links have been successfully used. The watt loss is about four times the loss for the same rating in air, this being due to the fact that increased cooling allows a higher current density to be employed. Tests show that the minimum fusing current increases as the head of oil over the fuse is increased, but actual figures are not at the moment available. The ratio of minimum fusing current in oil to minimum fusing current in air for a precisely similar arrangement of fuse wire and terminals depends upon the head of oil, but is of the order of 3 to 3·5 for a 5-inch head.

Types of Fusible Cut-outs.

Fusible cut-outs as a class may be divided into (1) open, (2) semi-enclosed, and (3) totally enclosed, of which the open type is now practically extinct. The semi-enclosed type usually takes the form of an insulating tube open at the ends, the fuse link passing down the centre of the tube; whilst the totally enclosed type consists of a tube completely filled with an insulating powder through which the fuse link passes. This filling material rapidly cools the generated gases by forcing them into the interstices of the powder, and thus effectually smothers the arc.

Potential Transformer Fuses.

These are designed for the express purpose of protecting the system from the effects of a short-circuit on the high-tension side of the potential transformer. It is generally recognized that it is necessary to use a resistance in series with these fuses, the value of the resistance depending upon the short-circuit kVA at that point. In metal-clad gear where the saving of space is important, one manufacturer has embodied this resistance in the fuse. This fuse is of the enclosed type and consists of a small-gauge wire of special alloy, the tube being filled with marble dust. This wire is itself of high resistance, and with extra-high-voltage gear a further saving of space is achieved by winding the wire spirally on an insulating core.

Schwietzer and Conrad Fuse.

The "S. & C.," "Empire," or carbon tetrachloride fuse consists of a glass tube filled with carbon tetrachloride containing a spiral spring the lower end of which is connected to the bottom ferrule. The upper end of the spring is attached to the fuse, which passes through a cork and is connected to the top ferrule. At the top of the spring and just below the cork is a funnel-shaped liquid-director. Melting of the fuse wire releases the spring, which then draws the moving terminal down to the bottom of the tube. Simultaneously with the introduction of this large gap the liquid extinguishes the arc, the rapidity of its action being accelerated by the liquid-director, which forces the liquid directly on to the moving terminal.

Switch-Fuses.

In this apparatus the blade or blades of an ordinary knife switch are replaced by fuses. The modern development for high-tension work is the oil-immersed switch-fuse, many of which are in use all over the country at voltages from 660 to 33 000. These switch-fuses are primarily intended as a cheap piece of apparatus for controlling a tee from a high-tension line in places where a circuit breaker is prohibitive. The fuse links are held under spring tension in the middle of a fairly large volume of oil and under a head of oil depending upon such factors as working voltage and requisite breaking capacity. Being totally enclosed and metal-clad these switch fuses can be safely used out-of-doors without any special covering. They may be used as single units or coupled together to form a complete panel. In addition, they can be arranged to line up with existing metal-clad switchgear, and arrangements are made for fitting current transformers for metering or protection purposes.

Standardization.

Efforts have been made from time to time to put cut-outs into one or more standard forms, and although we have a British Standard Specification (No. 88) it is rarely that a purchaser specifies that the apparatus which he is buying shall comply with this Specification. The Americans have gone very much further, the Specification of the National Electric Code being a thoroughly sound one and in constant use.

Mr. H. W. Kefford * says: "If we would foster the popularity of electrical applications and the prosperity of the industry we must create and maintain confidence in the safety, reliability, and convenience of electrical power by every possible means . . . the standardization of fuse design would undoubtedly conduce to economy in manufacture and result finally in a reduction of cost."

In conclusion, the author particularly wishes to thank Mr. H. W. Clothier for his helpful criticism of the paper in its draft stage.

APPENDIX 1.

Mechanism of Fusing.

The fundamental relationship up to the point of fusion of the wire is :—

Heat generated = Heat dissipated by conduction, convection and radiation.

By Newton's law of cooling the loss of heat per second is proportional to the difference between the temperature of the wire and the temperature of the enclosure, and experiment shows it to be proportional to the surface area of the wire. The gain of heat per second is proportional to I^2R, that is

$$\text{Heat generated} = 0\cdot 24I^2R, \quad \text{or} \quad 0\cdot 24I^2\rho l/\tfrac{1}{4}\pi d^2$$

where I = current flowing ;

ρ = specific resistance of copper ;

l and d = length and diameter of wire respectively.

$$\text{Heat dissipated} = e\pi dlT$$

where e is the emissivity of the material, i.e. the heat in calories radiated in one second from unit area when the temperature difference is 1 deg. C. ;

and T is the temperature difference ;

Then $$e\pi dlT = 0\cdot 24I^2\rho l/\tfrac{1}{4}\pi d^2$$

and $$T = 0\cdot 097\frac{I^2\rho}{ed^3} \quad \text{or} \quad I = d^{1\cdot 5}\sqrt{\left(\frac{Te}{0\cdot 097\rho}\right)}$$

This is the general form of Preece's formula, the expression under the root sign being reduced to one constant in the final form.

Example.—Copper fuse wires in air.

We have: Melting temperature of copper = 1 080° C.; air temperature (assumed) = 20° C., whence $T = 1\,060$; e for copper = $0\cdot 00035$; $\rho = 7 \times 10^7$ ohms per cm³.

This gives the minimum fusing current for

No. 18 S.W.G. = 97 amps.
No. 24 S.W.G. = 33·8 amps.
No. 30 S.W.G. = 12·7 amps. (cf. Table 1).

W. Wilson, in an article on time-element fuses * gives

$$\frac{1}{I^2} = \frac{a}{T_f}(1 - \epsilon^{-t/\tau})$$

where I = current flowing ;

$a = 0\cdot 24R/(Ae)$;

e = emissivity ;

A = cooling surface ;

R = resistance of fuse link ;

S = specific heat of material ;

$\tau = MS/(2\pi rle)$;

M = mass of fuse link ;

r = radius of wire ;

l = length of wire ;

t = time ;

T_f = fusing temperature.

It will be seen that for the minimum fusing current, t = infinity and $\epsilon^{-t/\tau}$ = zero. The equation therefore becomes

$$\frac{1}{I^2} = \frac{a}{T_f}$$

Example.—Copper fuse wires in air.

Minimum fusing current for

No. 18 S.W.G. = 98·5 amps.
No. 24 S.W.G. = 34·14 amps.
No. 30 S.W.G. = 12·88 amps. (cf. Table 1).

For lead wires C. P. Feldman † gives $I^2L^{0\cdot 5} = Ad^3$, where L and d are the length and diameter respectively in mm, and A has the value 1 350 for 150-gramme terminals, and 1 000 for 30—gramme terminals.

Example.—Lead wire in air, No. 18 S.W.G. ; length $2\tfrac{1}{2}$ in. ; terminals 30 grammes. Minimum fusing current = 14·7 amps. (cf. Table 1).

For aluminium plate fuses Schwartz and James ‡ give $I = K(b - 0\cdot 035)\,(t - 0\cdot 0024)$, where b and t are

* H. W. Kefford: "Standardization of Fuses," *Journal I.E.E.* 1910, vol. 48, p. 620.

* *World Power*, 1924, vol. 1, p. 91.

† *Electrician*, 1892, vol. 29, p. 87.

‡ *Ibid.*, 1905, vol. 56, p. 468.

the breadth and thickness respectively, and K has the following values:—

Length ..	2 in.	2·5 in.	3 in.	3·5 in.	4 in.
K ..	30 000	26 500	24 000	21 700	20 000

According to Preece's formula a No. 18 S.W.G. aluminium wire in air would have a minimum fusing current of 50 amperes, and according to the above formula an aluminium plate fuse having the same sectional area as the 18 S.W.G. wire (i.e. $b = 0 \cdot 15$ in. and $t = 0 \cdot 0125$ in.), would have a minimum fusing current of 63·5 amps.

APPENDIX 2.

Standardization.

In the interests of users, efforts have been made both here and abroad to standardize fusible cut-outs of various types, and Table 3 shows very broadly a comparison between some of the most important clauses in the regulations.

THE DIRECTION-FINDING EQUIPMENT AT NITON AND CULLERCOATS.*

By J. H. Reyner, B.Sc., Student.

(Abstract *of Paper read before the* London Students' Section, *28th November,* 1924.)

Summary.

The Niton and Cullercoats stations are the first to be equipped by the G.P.O. for a regular direction-finding service. The apparatus, which is of the well-known Bellini-Tosi pattern, is briefly described and the methods employed in taking a bearing are discussed.

The satisfactory installation of the apparatus is followed by a calibration in co-operation with a ship. Experience shows that this is absolutely necessary, owing to errors introduced by objects in the vicinity of the station. The method is described in detail, and the error curves obtained are analysed with reference to the local conditions.

The influence of neighbouring bodies on the error curve is investigated, and it is shown that the deviations obtained may be expected to remain constant. Experience indicates that this is true, so that a station which at first sight appears to be poorly situated may be capable of providing a reliable service if suitable precautions are observed.

Description of the Apparatus.

The apparatus employed for direction-finding consists essentially of a suitably erected frame aerial on which the particular station is received. The frame is rotated until the signal strength is zero or a minimum, at which point the frame is at right angles to the direction of propagation of the wave, i.e. the bearing of the station.

The equipment employed at the Niton and Cullercoats stations is of the Bellini-Tosi pattern, in which the simple rotatable loop is replaced by a system of two large loops erected accurately at right angles, the rotation being effected electrically.

The leads from the loops are connected to a radio-goniometer which comprises two field coils mutually at right angles, with a rotating search coil in the centre. An electric wave passing the aerial system induces currents in the loops, and these currents, passing round the appropriate field coils, set up magnetic fields in the goniometer. The resultant of these two fields (at right angles) can be shown to be fixed in direction and to have the same orientation relative to the field coils as the electric wave has to the external loops.

As the search coil is rotated, therefore, the signal strength will vary from a maximum to zero, the position of the zero depending on the direction from which the signal is coming, so that the final effect is the same as that of rotating one of the large loops.

Tuner and receiver.—For reasons of simplicity of operation and accuracy of results, it is now customary to employ a large search coil tightly coupled to the field coils, the loops themselves being untuned. The search coil circuit is tuned and loosely coupled to a "jigger" circuit, which is also tuned, the voltage across the condenser being applied to a seven-valve high-frequency amplifier, of which only three or four

valves are normally required. There are also two optional stages of note magnification.

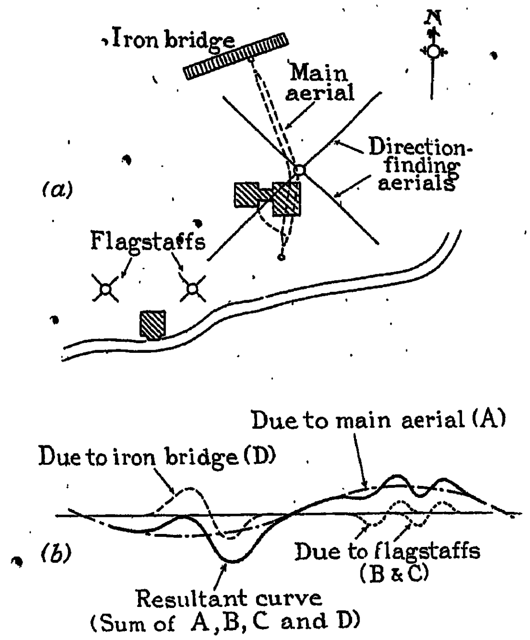

FIG. 2.

The middle points of the field coils of the goniometer are connected to earth, as otherwise electromotive forces are introduced due to the action of the frames as aerials. Such E.M.F.'s are independent of the direction of the signal and so lead to false bearings. The earthing is effected through a three-position switch. In the first position, the frames as a whole act as an aerial. In the second, the aerial effect is cut out and the direction of the signal may be obtained with the goniometer. There are, however, two zeros 180° apart. In the third position, therefore, the frame and aerial effects are combined to give a minimum in direction which indicates the true bearing.

To avoid "direct" pick-up, all the various units are screened. For further details of this system reference may be made to a work by R. Keen.*

METHOD OF TAKING A BEARING.

To take a bearing the approximate zeros are noted, and the "sense" of the bearing is determined. The actual zero points are then obtained by taking small swings on either side of the minimum, noting the readings at which the signals are of equal strength. The mean of the two readings gives the actual zero. This method is adopted because the zero itself is indeterminate over 2 or 3 degrees.

In addition to the true bearing, the reciprocal is also observed, and 180° added or subtracted as required. These two bearings, which form a pair, should agree, and as many pairs as possible are taken in the time available (usually one minute). If the bearings in a pair do not agree it indicates that some aerial effect is present, so that the bearing obtained is not correct. A dis-

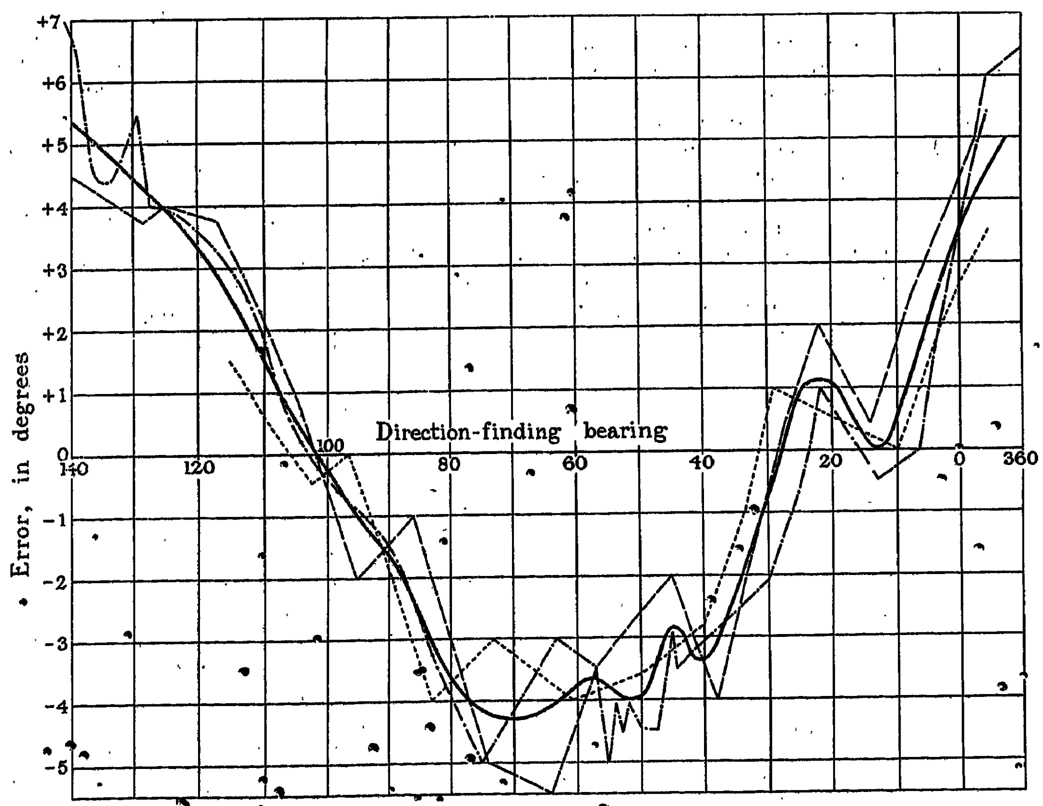

FIG. 3.—Error curve at Cullercoats.

crepancy of 2° is permitted ; if the difference is greater, the bearing is repeated. The main aerial of the station is disconnected during the taking of a bearing, as otherwise all bearings are found to be in the plane of the aerial.

Calibration.

The apparatus, when installed, must be calibrated. The goniometer is adjusted approximately by taking bearings on known fixed stations, but it is necessary to employ a ship to steam over the effective arc, sending signals every few degrees.

The actual bearing at these points is determined by visual observation with a theodolite, and the error can thus be plotted. The curves usually contain unexpected irregularities, indicating that a calibration of this sort is essential.

Analysis of Results.

The Niton error curve is shown in Fig. 1. Three runs were made over the arc, and these are in reasonable agreement (allowing for operation errors). A mean curve is drawn through the three.

The sector 85° to 115° is classed as unreliable, the deviations from the mean curve being too large. The curve itself is also too steep ; e.g. at 111° an operation error of ½° would make a difference of 2° in the true bearing. The coast line at Niton makes angles of 85° and 310°, so that this is probably due to coast effect, it being well known that bearings within 20° of the coast line are unreliable. The sector 55° to 85° is again reliable, but there is a permanent error due to coast refraction.

Referring next to the irregularities on the curve, these can be shown to be due to objects in the vicinity. Fig. 2 (*a*) shows the surroundings of the Niton station, there being several masses of metal quite close to the aerial system. These objects have currents induced in them, which set up secondary radiations combining with the main radiation and tending to distort all the bearings in that region into the plane of the metallic mass. Thus the main aerial, even though disconnected, tends to distort all bearings into its own plane (here 180°), giving rise to an error curve as at A in Fig. 2 (*b*). This curve is the principal error and is termed a " quadrantal " error, being alternately positive and negative in the four quadrants.

Next, the flagstaffs at 215° and 235° distort the bearings into these planes, e.g. 213° will appear slightly more, and 217° slightly less. This effect is only apparent on bearings from the south-west, and gives rise to two small curves B and C in Fig. 2 (*b*). Finally the iron bridge, though behind the station, will distort bearings from the south-east into the plane 320° (140°), as shown in curve D. Since the bridge is behind the station, curve D is reversed compared with B and C. The sum of all these effects will be seen to resemble the actual curve very closely over the sector 115° to 260°.

The error curve for Cullercoats is shown in Fig. 3. It will be seen to be composed of a quadrantal error, due to the main aerial as before, with three deviations superposed. The curve is thus of the same form as at Niton, and could be built up in the same way.

If this explanation of the deviations is correct, the error curves may be expected to remain constant; and experience indicates that this is the case, so that these calibrations may be considered to be reliable. As an additional precaution, however, they are periodically re-checked.

Conclusions.

The following conclusions may be drawn :—

(1) It is essential to calibrate a new direction-finding station over the whole of the effective arc, which extends up to 20° from the coast line. Check-bearings on fixed stations are only useful for preliminary adjustments.

(2) The error curves usually take the form of a quadrantal error due to the main aerial of the station, with minor deviations occasioned by any metallic masses in the vicinity.

(3) The deviations appear to be caused by re-radiation from the various objects, such re-radiation being in a direction tending to distort the bearings into the plane of the interfering objects.

In conclusion, the author wishes to express his thanks to the Post Office authorities for permission to publish the information given in the paper, and to those of his colleagues who have assisted in the analysis thereof.

ECONOMICS AND INDUSTRIAL ELECTRIFICATION.*

By A. TUSTIN, M.Sc., Student.

(*Paper read before the* NORTH-WESTERN STUDENTS' SECTION, 11*th November*, 1924.)

SUMMARY.

This paper attempts to define exactly at what we should aim in a policy of power supply, and discusses how we may decide which among the many alternatives will best achieve this aim.

In this connection it is found necessary to discuss :—

(1) The degree of dependence of our foreign trade upon cheap power.

(2) The implications of the ordinary methods of comparing the economy of various schemes.

Lines of investigation are suggested by which the best policy may be selected, and the methods of charging for power which it would be desirable to adopt are discussed.

POWER SUPPLY.

Comparative estimates for power proposals.—It is desirable before discussing alternatives of policy to state very clearly at what result the policy aims, so that a standard will be available by which the alternatives may be compared.

This is neglected by writers on power supply, who usually stress beyond proportion some particular alleged benefit expected to follow the application of their proposals, for example the conservation of our coal resources, or the making of nitrates within the Empire. More commonly they are content to prove that their proposals would enable power to be generated at a lower cost per unit than at present, and they assume that every one will agree that this is a desirable thing.

Power costs and foreign trade.—The universal argument advanced in support of cheap power is that it would enable us to compete with more success in the markets of the world. It is worth while to examine this argument, and to state clearly that—

(1) Whatever our costs of production, we shall always be only just able to compete abroad.

(2) The increase in the standard of living which a power scheme would make possible would be extremely small.

To establish these most important points it is necessary to outline certain principles of foreign trade.

The error which it is important to avoid is the assumption that because a country, say Russia, can manufacture, say, iron goods more cheaply than England, then it will be impossible for England to supply the world's markets in the face of Russian competition. This is not necessarily true. Leaving out all the complication of other countries and products, let us suppose that Russia also produces wheat, and produces it not only cheaper than the same quantity could be grown in England, but also proportionately cheaper that Russian iron (by "cheaper" being meant "at less expenditure of labour and capital," not cheaper in the monetary sense, since, owing to goods in Russia being priced in roubles and goods in England in sterling, which of the two is the cheaper in money depends entirely upon the rate of exchange).

Suppose now, as at first seems probable, English merchants purchased both iron and wheat in Russia. The result would be that English money would accumulate in Russia, where it is useless unless it is used to purchase goods in England. The level of value of English money in Russia would therefore fall. As it fell it would first pass the limit where iron ceases to be cheaper to buy in Russia than in England. A little farther on it would become profitable to buy iron in England, and sell it to Russia. The conditions for a steady mutual trade would now exist, and it will be seen that—

(*a*) England would make iron goods and exchange them for Russian wheat.

(*b*) The maximum real economy is secured in this way.

(*c*) There exists some ratio of monetary exchange at which merchants on both sides could make a profit.

If the currency were gold instead of notes the above argument would still hold good, only, instead of the ratio of exchange altering, the price levels of the two countries would move oppositely under the influence of gold payments and exactly the same result would be obtained.

The above fictitious example is not intended to be more than a sort of mental diagram, which may convey this important idea to those to whom it is not already familiar. It is an example of a general principle which applies throughout the most elaborate processes of exchange.

This country is destined to an industrial development growing more dense rather than less dense, not only because it is fairly well suited to manufacturing, but also, and more significantly, because it is relatively unsuited for anything else. We shall be able to compete abroad not because we have cheap power, which is a small matter, but because we can neither decrease the population of these islands nor transfer our huge fixed capital abroad. The logic of events will reduce our standard of living until we just do compete, and the irrational optimism of human nature will try to see to it that we just do not. A fluctuating equilibrium will be attained, and it must always seem, as it seems to-day, that only a little extra is needed to turn the scale, and

* A Students' Premium was awarded by the Council for this paper, and it is the practice of the Council in such cases to publish the paper, in full or in abstract, in the *Journal*.

that 5 per cent off this or that would establish our markets on a firm basis. It is like watching the lap of the waves and forgetting the tides.

So far as power is concerned the author contends that, if all our coal were destroyed to-morrow, we should import coal and perhaps electrical energy and develop very expensive water and tidal power, and apart from temporary disorganization we should carry on in the long run with very little change in our standard of living. It follows that cheap power has practically no effect on our ability to compete in the world's markets, and also that we need give no thought to the possible exhaustion of our 500 years' supply of coal.

The change in our standard of living which a scheme of electrification would make possible would be equal to the proportion of the cost of production of our whole national output which it saved. This would be extremely small. To get the subject into focus let us consider a few approximate figures. The present cost of production of the whole annual products of the United Kingdom is greater than £3 000 000 000. The annual cost of the coal used for power production taken at £1 per ton is about £80 000 000, or 2·6 per cent of the costs of production for the country. The cost of the coal used in generating electricity in power stations is about £7 000 000, or 0·23 per cent of the costs of production.

Figures for the individual industries entirely confirm these averages. The largest industry is agriculture, where the cost of power is negligible. For coal mining, where the waste of coal in steam-raising is notorious, and where the fuel actually burned is often of low grade, only 17 million tons are burned in producing 270 million tons. The fuel cost is therefore necessarily less than 17/270, i.e. 6·3 per cent of the cost of production.

In the textile industry the following are the approximate figures, which are based upon official averages for the trade :—

Mule spinning.—In a typical mill the cost of coal is 4·9 per cent of the cost of production, excluding the cost of raw material and commercial charges.

Ring spinning.—The percentage is slightly less.

For the whole textile industry the coal used per head is about 8 tons per employee per annum.

For a typical electrical engineering factory about 6 tons of coal per employee in the works (excluding offices) are used per annum. This includes coal for all purposes, heating, lighting, cooking, and forge fires. This represents about 4·5 per cent of the cost of production, excluding raw material.

Electrification could save only on fuel costs, and part of the saving would be offset by the capital outlay, and it is therefore clear that a saving of a small part of 5 per cent only is all that can be hoped for at the best from power reform. Those prophets who base their hopes of prosperous times upon improved power supply will therefore be disappointed. All saving, however, is good, and though the proportion is small the total is large.

Power supply policy.—Setting aside therefore baseless hopes and ill-considered standards, we may ask the question "What are we really aiming at in a scheme of power supply, and how can the merits of the many alternatives be compared?" Electrification is, after all, only a method of indirect production, and must only be employed when it is the method of production most fruitful of value. It is hard to see why there is a cry for cheaper power, and not for cheaper machinery or lower railway rates. Just as no one would suggest huge and costly developments of machinery manufacture in order to produce cheaper machinery, so any artificial treatment of power production must avoid diverting resources to development which may not be in the general interests of the nation.

We must admit that the standard of living of a people cannot be greater than that of the rest of the world unless they have greater resources, or handle their limited resources with greater skill. The author feels that this people can only avoid a very unprosperous half-century by the absolute elimination of waste, not only of power but of every value, and by the deliberate adoption of a policy of insisting with the utmost realism upon those forms of effort and development which will give the greatest return of real human value for effort involved. This is what we mean by real economy, and our aim in power policy is to secure the maximum economy in this sense, that it should contribute to the maximum to the real human value which our national effort can secure.

No one is likely to dispute that in course of time our power supply system must be developed on the general lines of larger stations, defined districts, and interconnection of supply. At the same time, there are widely different possibilities with regard to the rate of development and the ultimate intensity, with a view to which the lines of present development are to be decided. Some more exact definition of our requirements is therefore needed. The cheapening of the cost of power per unit which is advocated would usually apply only to an increased production and consumption of electrical power. Visualizing a more and more intensive electrification, it is clear that the cost of energy would progressively decrease, though, after a certain stage, only slowly.

The amount of electrical power which industry will use is a function of its price. The lower the price the more will be used, but not to an indefinitely large amount. Clearly, then, if electrification is to be extended the basic question is: "Which falls the more quickly as electrification is increased, the cost of generation or the price at which industry will take the increased quantity?" At some point there is a limit, which corresponds to the ordinary commercial limit, beyond which electrification does not "pay." This limit may be very different from that which would be thought of if one set out merely to produce a scheme which would give cheap power. There must be a proper comparison of cost and return so that the limit beyond which electrical development does not "pay" may be found. An important question about this limit is whether, when found, by analysis or experiment, it corresponds to the true best national policy, or whether public policy must with truer vision transcend this "wrangling of the market place" and deliberately use national resources to secure national advantages which are left out of the commercial balance sheets. This question, of course, verges on politics, but political argument will not answer

it. It is a technical problem and depends for its answer upon a consideration of how costs are arrived at, just what realities they include and what they omit.

For this reason, and to attempt to clear up certain difficulties in the use of comparative estimates in every-day practice, in the next section an analysis is given of the way in which costs and values are compared.

The Correct Measurement of Comparative Economy.

It has been agreed that real economy is the return in human value for effort involved. Since in ultimate analysis both value and effort are matters of individual feeling and not of reason, true economy can never be logically defined except with explicit reference to the will of the people. Economy, and even comparative economy, are not constant—they are in their nature elusive and indefinable things, matters of taste. The ordinary commercial standard of economy, that of profit, the difference between cost and value, has the great merit that it does reflect in some way this popular valuation, which is simply demand and supply. Because of this the author thinks that cost and commercial value will always be important and useful measures of economy, but it will be necessary to find out just what the implications of this standard are, and how far the judgments of value which its adoption implies are really those which would be consciously endorsed by the community. That commercial estimates omit many things will be obvious, but as a small concrete example we might take air pollution. Smoke costs London annually £17 000 000, and England £200 000 000, and these sums enter into no comparative estimate and appear on no balance sheet. In public enterprises, such as power supply must necessarily be, such considerations are not without real significance.

Commercial comparative estimates.—It will therefore be worth while to examine the way in which comparative estimates are usually made. The simplest type of economic problem is one which concerns material alone, like those in mathematical textbooks about making the largest possible tin can out of a sheet of tin. So long as we are dealing with material of one sort, say comparing one set of machinery with another, or comparing the economy of a large quantity of cheap coal with a less quantity of expensive coal, there is no doubt that we can safely compare their costs. Actually, however, we have also to find some basis to compare expenses of different kinds. For example, the whole question of power development concerns a proposal to expend a great amount of work upon power stations in order to save continual work upon coal mining.

We are really making two comparisons here. In the first place we are comparing work done on power stations with work done in coal mining, and we compare the money costs of both. Do we really believe that the relative desirability of diverting people towards the labour of mining rather than the labour of engineering is exactly measured by the relative lowness of miners' wages?

In the second place we are comparing work done now with continual work done in the future. This is very simply done in current discussions by the adoption of the money costs of both and the reduction of capital costs to an annual cost by the use of the rate of interest. Apart from the fact that the real rate of interest referred to standard securities fluctuates widely and can seldom be measured by 5 per cent, can we really be satisfied that this method gives a true standard of comparison?

Furthermore, development of capital can only be made at the expense of current consumption. During the active phases of the industrial revolution the people of this country had not enough to eat, whilst hundreds of millions of pounds were being sunk in building factories and railways; but no doubt the desirability of so diverting current consumption to capitalization was measured, if not by 5 per cent then by some equally haphazard figure. Equally there are periods when our productive machinery and labour are half idle and it is still thought public policy to calculate on this 5 per cent before setting them to public work. It would therefore seem that (1) for public enterprises considerations of public policy should not take too much account of this 5 per cent, and that (2) private enterprises might pay some attention to the actual rate of real interest which will probably hold during the life of the plant, including all changes in price-levels. If the private enterpriser thinks that this and similar points are not sound finance, one can only add that by neglecting them he forgoes enterprises which would have yielded him more profit than he otherwise gets, and he accepts obligations which yield him less profit, neither of which is part of the function of an efficient private enterprise.

Kelvin's Law.

Among the problems which involve the rate of interest the best known are those of the type of Kelvin's law for the economical size of a conductor. It is well known because it admits of a simple mathematical solution, the answer being that the size is correct when the annual cost of the conductor (as measured by the rate of interest multiplied by the first cost) is equal to the annual cost of the energy lost in it. It is rare that the conditions are so simple that a mathematical solution can be found to problems in engineering economics. Even Kelvin's law is not quite true as it assumes a straight-line relationship between the cost and the copper section; and it neglects voltage-drop and heating limits. Such problems are invariably solved by comparative estimates with a series of variations, and the result is, of course, that we choose what the right answer would have been if we had taken every condition into account and had been able to solve the resulting equations. The value of Kelvin's law is chiefly mental. To have once become really aware of this type of argument greatly helps one's understanding. By acquiring a sort of mental framework of such ideal problems we are able to think more clearly and with greater ease about actual problems. In practical application the author would rather invert the emphasis on Kelvin's law and say that it does not show the importance of selecting the cable of economical section, but rather its unimportance; since it shows that for even a large variation from the most economical size the increase in cost tends to be counterbalanced by the saving of

energy, i.e. the curve of total annual cost is very flat-bottomed.

DEPRECIATION.

Since everything tends to deteriorate in the course of time, it is necessary in comparing economy to allow for depreciation. Money may always be invested in standard securities, where it will earn a certain rate of interest. If the alternative presents itself of investing the sum in plant, it is clearly wrong to say that the money should be invested in plant if it will earn as much as or more than the income which it would earn if invested in securities, because after, say, 25 years the plant will be worn out but the securities will still have their full value. To find when the two investments become of equal value is simply a matter of arithmetic. It is simply required to find what annual return lasting 25 years only is an adequate return for the complete abandonment of a sum of money for ever. This neglects any value of the "going concern" as giving a value to the opportunity of replacement. Exactly the same answer of course would be obtained if the problem were put the other way round, i.e. "It is required to find the present value of this particular income which lasts for 25 years." In fact the latter is a better way to put it, because it allows for the fact that the income may be spread unevenly over the 25 years. It would in this case still be possible to calculate its equivalent present value, and to say that this value is equal to the maximum capital expense which such a prospect of income would justify.

The necessary "ratio of interest and depreciation" for various "lives" at various rates of interest are easily calculated, but as they are given in tables for the present value of terminable annuities this saves the trouble of calculating them. It is worth while calling attention to the fact that the choice of the right depreciation rate is exactly of the same degree of importance in comparative estimates as the right estimation of the capital cost. To estimate capital outlay minutely and then be uncertain as to whether to use 8 per cent or 12 per cent as a correct interest factor is illogical, because 12 per cent taken instead of 8 per cent is exactly equivalent to and indistinguishable from an increase of the capital cost by 50 per cent. The following table will give an idea of how the right figure varies.

Years of life	Percentage rate	Interest and depreciation, per cent
10	5	12·9
15	4	9·0
	5	9·63
	6	10·3
	7	11·1
20	4	7·36
	5	8·02
	6	8·72
	7	9·45
30	4	5·78
	7	8·06

Depreciation in accountancy.—The endless argument about the correct charging of depreciation in cost accounts has arisen from a failure to distinguish clearly the different purposes which a depreciation charge is expected to meet. Since these several purposes can only be correctly attained by quite different methods of charging, the confusion is understandable.

Some of the requirements are :—

(1) To maintain the balance sheet in a condition which shows the true state of the firm, or, as required, some other state.
(2) To provide a fund for the replacement of the plant at the end of its life.
(3) To give a guide to values in the case of sale, scrapping or replacement.
(4) To arrive at true factory costs for selling.

Further to these requirements, bookkeepers have added muddled ideas borrowed from the depreciation for comparison of economy described above, and the whole argument has been complicated by the curious popular fallacy that the value of an article depends upon how much was paid for it and how much has been written off since. This discussion will not now be carried further, but it is inserted as a warning against attention being paid to the bookkeepers' ideas of depreciation.

Obsolescence.—The power of a piece of apparatus to earn income, i.e. its value, may disappear, for other than physical reasons. It obviously does not matter how it disappears ; the depreciation charge must correspond to the probable duration of the earning power, and, if it does so, everything is allowed for. An obsolescence charge does not differ in principle from a depreciation charge. Obsolescence is all depreciation which does not arise from the plant itself, but from outside causes. Such a charge is quite valid and necessary in comparing economy. The fact that it cannot be determined in advance for certain when a plant may lose its earning power is no reason for neglecting the possibility. The estimate should be based on the estimated probabilities.

An example of obsolescence is seen in a comparison of the use of gas engines as opposed to oil engines on oil fields, to utilize the natural gas which is often available. The supply of such gas very often falls off after some time, and on that account Diesel or steam engines are often installed from the beginning. There is no reason, however, why the judgment should not be helped by comparative estimates based on the probable duration of the gas supply, and this factor would be accurately taken care of by the appropriate higher depreciation rate corresponding to the short probable useful life of the gas engines.

An interesting cause of "obsolescence" is technical progress. Commercially it is obvious that the chance of a new competitive process springing up is a chance that any plant may lose its value. It is a striking paradox that a discovery that enriches mankind as a whole automatically destroys the value of the property of certain persons.

In connection with power supply, due consideration should be given to the quite considerable probability

that technical advances will be made during the next decade or two which will render our present generating practice obsolete; one thinks in this connection of super pressures, gas turbines, low-temperature carbonization, cheaper transmission, or even new sources of energy. Perhaps electricity will become a by-product, and in this case its price may fall to any low value. Are we certain that any line of development we adopt to-day will still be the right line of development in 20 years' time? Technical progress was never so rapid as it is to-day. All these possibilities are properly taken into account by allowing a rate of depreciation which includes for "probable obsolescence" and loads the balance against all proposals to sink large values in premature development.

The Accountancy of Real Values.

The foregoing discussion of the usual methods of making commercial comparisons has shown that they can only go part of the way towards making the real economy as large as possible, because there are very many facts which are left out of account altogether. In the public supply of electricity, policy cannot be determined without an implicit decision upon this preliminary question of how far the ordinary commercial standards of profitableness must bind public policy. The question now at issue is whether the Government must of necessity either not touch financial matters or, if it does, be bound by the same necessity of showing a monetary return for all its monetary expenses and investments as binds a private firm. This suggests possible functions of the Government quite distinct from those functions, which all will admit, of co-ordination, certain legislative control, the prevention of monopoly exploitation, and constructive guidance.

To be able to answer such questions is a great need of our times, and the author feels sure that the appropriate analysis and an accountancy of real values will be built up in the future. He suggests that, failing this more complete analysis, rigorous estimates on the lines of commercial estimates must be made and must bind decisions, but that it is permissible for, and indeed a function of, the Government to include in these estimates a monetary equivalent of national values, or of national disadvantages, which would not enter into the determination of policy if left to private enterprise. Hence Government enterprises need not "pay" on a cash basis, but they must pay on a basis of the accountancy of national values. The chief value of the commercial system is that it provides automatic adjustments and checks, but there is no reason why its advantages should not be retained in national enterprise by proper accountancy. There is no real reason why charges should be equal to the actual cash paid. The function of such accountancy is that of a scoring board in a game. It is important that the real "values" be marked up independently of what it may be convenient or necessary to pay in cash. For example, unpleasant trades might be discouraged by a higher "wage" for purposes of this scoring-board accountancy, without necessitating the actual payment of higher wages in that trade. This is of course impossible except in communal enterprises.

Apart from these deliberate and defined departures from commercial economy, it seems to the author that the ordinary commercial limits must be rigorously adhered to, because to cut adrift from them leaves us without any anchorage at all, free to follow some ideal wherever it may lead, which is only all right so long as we leave nothing out of account, and in the world of ideas it is easy to leave out some factor which would have been unpleasantly obvious in a balance sheet and which the "wrangling of the market place" would not have neglected.

The selling of energy.—The author has shown that producers of energy under any system must sell at such prices as will show no loss. A proposed system must justify itself by being able to build up its load soon enough to give a return on the capital invested. The reduction of the income expected during the life of the plant to an equivalent present value would be carried out on the lines already indicated. This income would probably be distributed very unevenly throughout the life of the plant. The return for the first several years of the inauguration of a scheme of power reorganization might economically be negative in some cases, that is, it might be economical to sell energy below net cost. This does not mean that it should be sold only below gross cost, which is, of course, a commonly accepted principle, for if a new supply system would be otherwise underloaded it obviously pays to accept load at a price which only includes the fuel and labour charges dependent upon this extra load, and not the interest, rent, taxes, etc., which have to be paid in any case, provided that the load otherwise could not be obtained. This, however, is selling at real cost so far as these extra units go, not below cost.

In an exactly similar way it might pay in some cases to sell some power below the apparent net extra cost of producing these units. This is because as we consider a series of schemes of progressively more intensive electrification the efficiency will in every way be progressively higher, and with each imaginary addition to the output the cost of production of *all* the units generated may be imagined to fall slightly. Hence the additional cost of generating additional units is really less than the cost taken at the average for the station, i.e. we are concerned with marginal cost, which is in this case below the average cost. It is debatable whether a power supply undertaking could economically make still further cuts in price over a period of years for the purpose of building up load. This question is of some importance in view of the developed nature of the industries of this country, which will make all those processes of conversion based upon normal power prices extremely slow. An artificial "dumping" of energy in a defined area to *new* customers for a limited period sufficient to encourage immediate conversion to electric drive in a large number of factories would tend to raise the load at once, and bring into line those conversions which otherwise would have been scattered over a long period. If the employment of this device would make possible the installation of a power system which would otherwise have been impossible, the author sees no reason in economics, law, equity or public policy, why it should not be deliberately employed. Without

such a device, in cases where plant is replaced piecemeal as elements wear out, it seems possible that a technically out-of-date plant might have its existence indefinitely prolonged without a complete reorganization ever appearing profitable.

Methods of charging.—In general there are available two quite different systems upon which the charges of a monopoly undertaking may be based. The first is that of cost plus profit, "cost" of course taking into account load and power factors and all the circumstances of supply. The other is called by two alternative titles, according as the speaker is a supplier or a consumer. The supplier calls it "Selling at the value of the service," the consumer "Charging the maximum monopoly revenue." Economists sometimes call it "Charging what the traffic will bear." The author has assumed in the above discussion that this is the principle which will and should be adopted in selling electrical energy, and the reasons for this will now be given.

Selling at monopoly prices.—That the public interest may best be served by a public supplier charging as much as he can get is only true if his receipts are not spent upon private diversion, but used to enable a corresponding amount of product, which would otherwise not be produced, to be sold below apparent cost. This argument is therefore no defence of private monopoly without restriction.

An attempt will be made to justify the statement that on the average a public supplier should sell at cost, but that for the separate parts of his production he should sell for the maximum he can get. In all cases of joint supply, of which electricity supply is an example, there is really no such thing as a cost for each particular part of the output. There is a cost of raising sheep, for example, but no separate costs of producing wool and mutton respectively. If the demand for mutton were low enough (as in Australia before refrigeration) one might have to pay a man to bury it, yet it would still be produced, and if a penny a pound could be obtained for it it would be sold "profitably" at that price. No one would contend that in a theatre each seat in the stalls really costs, to install and maintain, six times as much as a seat in the gallery. On the average all the seats in a theatre together just about pay the expenses of running. If all the seats were charged at this average price the theatre would be less used, as those who use the cheap seats would not be likely to pay much extra for the chance of getting a front seat. The running of that theatre would therefore be impossible, and all those who previously got an entertainment worth more to them than the amount they paid (otherwise they would not have come) must now be without that opportunity. In this case, then, charging what the service will bear seems socially justifiable. Half a power system is economically very like half a theatre. It is worth while putting in a gallery and charging less than apparent cost. It is right to charge stall-holders the maximum they can be made to pay in order to enable this to be done; and it would be manifestly unjust to charge as much for bad seats as for good, because they cost the same. The argument usually advanced against this position is one which mistakes its real intention. For instance, it would be proposed to charge a very high rate for lighting in a select suburb, as these consumers would rather pay a high rate than go without the amenities of electric light. It is then argued that the high prices for lighting restrict its use below the natural economic level. This is obviously the reverse of the truth, for the whole aim of the rate is to be low enough (even if only just low enough) to secure that particular market, and the extra income thus obtained may be used to extend the sale of electric light below apparent cost in suburbs which are not select. The adoption of this policy might multiply the use of electric light to an indefinitely great extent if a large field were just upon the margin of use. The same principle of differential charging is used to fix railway charges, and though the strange apparent anomalies of railway rates are criticized by those who have most to pay, there is no doubt that they have made possible the development of our railway system.

Superficially a system of charging what each consumer can be made to pay seems unjust. For example, a mill may have been electrified for some time. If the owners then find that on the occasion of power system extensions a neighbouring mill, to persuade it to make a change-over, is offered a very much lower tariff, they may ask for a reduction also. The fact is, however, that the real cost of electricity supplied to the second mill actually is very low as it is an extension of the existing system, and only on the basis of charging a low price and on no other system can the advantages of this real economy be made available to the nation.

It is not necessary that the absolute maximum monopoly revenue should be sought from consumers who could ill afford to go without electricity, nor is it suggested that electricity should ever be supplied below the bare cost of generation for that particular demand, the special circumstances of a temporary low price already mentioned being allowed for. The real theoretical position seems to be that sales should be carried to the limit that is fixed by the marginal cost of production, and not the average cost of production, and by the marginal value of supply to the consumers, not the average value of supply. For consumers other than those at the margin the price should be low enough to induce and maintain the market, and the average price should be high enough to cover total inclusive costs. In short, while this paper suggests that though electrical development must justify itself on a basis of earning power, it is at the same time allowed the benefit of driving a bargain, in the knowledge that an industry will not pay for electricity more than the value of the benefit which that industry obtains from it. This higher value of electricity in certain applications must be properly accounted on the "scoring board" which the system of charging really is, and this accounting will, so far as it goes, enable the true maximum of real value to be obtained.

The adoption of such principles for charging, together with the inclusion in comparative estimates of those factors which market prices neglect, appears to be the basis needed at the present time in order to secure some agreement among the many advocates of power reform.

INSTITUTION NOTES.

International Conference on E.H.T. Lines.

The Secretary has been requested to draw attention to the following Note which appeared in No. 346 (October 1925) of the *Journal* :—

It is proposed, subject to there being a sufficient demand, to publish an English edition (in two volumes of about 1 100 pages each) of the papers read at the International Conference on E.H.T. Lines held in Paris from the 16th to the 25th June, 1925. The volumes will also contain a report of the discussions.

If the demand reaches 400 copies, the price will be £4 for the two volumes, but in the event of 800 copies being subscribed for, the price will be £2 10s.

In order that an early decision may be arrived at as to whether to publish an English edition, those wishing to subscribe for copies are requested to inform without delay.

Monsieur Tribot Laspière,
Union des Syndicats de l'Électricité,
25, Boulevard Malesherbes,
Paris,

of the number of copies they will require.

A French edition of the papers and discussions will also be published, provided not less than 1 000 sets are subscribed for. The price will be 200 francs per set, but after the 1st November, 1925, the price will be increased to 250 francs. Orders for the French edition should also be sent to M. Tribot Laspière at the address given above.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 September–25 October, 1925 :—

OBITUARY NOTICES.

WILLIAM ARNOT was born in Glasgow in 1854 and was educated at Hamilton Academy. He began his career as an engineer in 1880 when he came to London. From 1880 to 1892 he was in the employment of various companies, including the London Electric Supply Corporation and the India Rubber, Gutta Percha and Telegraph Works Co., Ltd., at Silvertown. In 1892 he was appointed the first engineer to the Electricity Department of the Glasgow Corporation, and he held that post until 1896. During this period the Electricity Department was under the control of a Sub-Committee of the Gas Department. The generating station at Waterloo-street, Glasgow, was designed and equipped by Sir Alexander Kennedy, under the superintendence of Mr. Arnot. As the demand for electricity continued to grow Mr. Arnot initiated and carried to fruition the policy whereby two large sites were acquired for new generating stations, one at Port Dundas on the north side of the River Clyde, and the other at St. Andrew's Cross on the south side of the river. Port Dundas station ultimately contained 38 000 kW of plant, and St. Andrew's Cross station 22 000 kW of plant. These two stations were gradually developed until they could accommodate no more plant, but they sufficed to meet the Glasgow demand until 1912, when the site of the Dalmarnock power station was acquired. Mr. Arnot resigned his post as chief electrical engineer to the Glasgow Corporation in 1897, when he commenced business as a consulting engineer in Glasgow. He acted as consulting engineer to the Govan Corporation, for whom he designed and equipped a complete undertaking, including a generating station with a plant capacity of 4 000 kW, and all the underground mains and cables. He also carried out a large number of private installations throughout England and Scotland, including Dunrobin Castle and Quarrier's Homes, Bridge of Weir, and his services were retained by the Town Councils of Wick, Lerwick, Brora and other towns in the north of Scotland. He also acted as consulting engineer in this country for the Rand Water Board, and carried out a large amount of inspection work for them both in Britain and on the Continent. Mr. Arnot was one of the pioneers in connection with the electricity supply industry, and foresaw the main features of the development of the industry which have taken place. He was a man of even temper, and of a quiet and retiring disposition, and he retained throughout his life the confidence and esteem not only of his large clientele but of his wide circle of friends in the industry. He died in Glasgow on the 25th June, 1925. He was elected a Member of the Institution in 1891.

W. W. L.

SIR WILLIAM F. BARRETT, F.R.S., died on the 26th May, 1925, in his 82nd year, and in him physical science has lost a devoted adherent and worker. He received his early education at the Old Trafford Grammar School, Manchester, and in 1863, when only 19 years of age, became assistant to the late Prof. Tyndall, Professor of Natural Philosophy in the Laboratories of the Royal Institution. Under this great master of science he must have received much stimulation of his natural taste of acquiring and increasing his scientific knowledge. In 1867 he was appointed assistant master at the International College, and was lecturer in physics at the Royal School of Naval Architects until 1873. His chief life's work was in connection with the Chair of Physics at the Royal College of Science, Dublin, which position he filled with much distinction for no less than 37 years, that is until 1908. He carried out his work there with great success, training many students of note. In 1899 he was elected a Fellow of the Royal Society and was knighted in 1912. He was one of the founders of the Physical Society of London in 1874, and along with Guthrie was chiefly instrumental in organizing that body. He also collaborated with Guthrie in fostering the summer courses for science teachers which the Science and Art Department originated in 1871. These courses were probably the first attempt to introduce the systematic teaching of practical physics and were attended by teachers from all parts of the country. He was a prominent member of the Royal Dublin Society, to which body he communicated several important papers, as he did also to the Royal Society and to the Institution. He was also a well-known figure at many of the meetings of the British Association, to which body he contributed interesting papers, and served on several of its committees. After his retirement in 1908 from the Chair of Physics at the Royal College of Science, Dublin, he still maintained his interest in scientific matters, frequently attending meetings of the Royal Society and other bodies.

The writer has been asked to communicate this brief appreciation of Sir William Barrett's life work, no doubt on account of his personal association with Sir William whilst research work was being carried out between the years 1896 and 1902. Regarding this work, the writer can bear the fullest and most cordial testimony to the great interest, time, labour and skill shown by the deceased scientist.

Sir William was greatly attracted by the work of Dr. G. Gore, F.R.S., who was probably the first to discover the peculiar behaviour of various specimens of iron which showed certain critical points during

heating and cooling. This led him to make further investigations and to his discovery of the peculiar behaviour and property, now termed "recalescence," in steel. It was largely due to these results that methods of examining various types of steel, each more or less possessing its own idiosyncracies, by preparing heating and cooling curves, were established. Between 1883 and 1902 the writer was discovering and developing his various new alloys of iron with other elements, and amongst other prominent scientists of those times, including engineers, electricians, metallurgists, chemists and physicists, with whom he came in contact and discussed his numerous researches on alloys of iron with other elements, was Sir William, whose acquaintance he first made in 1887. Sir William had a keen mind with a long and wide experience in carrying out experiments of a physical character, and he became intensely interested in the writer's many alloys of iron and carried out a large number of experiments on the magnetic, resistance, permeability and other electrical properties of the manganese steel discovered and made by the writer. These physical experiments and the results were described by Sir William in three papers to the British Association and the Royal Dublin Society, read in 1886–9. Subsequently the writer supplied a large number of specially prepared small specimens of his various alloys of iron with carbon, chromium, nickel, tungsten, silicon, aluminium and other elements in order that Sir William might test them in a similar manner. As a result, Sir William found that some of the alloys of iron and silicon, also of iron and aluminium, possessed valuable magnetic and electrical characteristics, including their low-hysteresis and high-resistance qualities. The results of such tests were described at length in joint papers by Sir William, Mr. (now Professor) W. Brown (who had assisted at the experiments) and the present writer, read before the Royal Dublin Society in 1899, 1902 and 1904, and also before the Institution in 1902. The important practical results which some years later were obtained and their service in the development of electrical equipment are too well known to call for more detailed mention here, but afford a striking instance of the value of co-ordination of the work of investigators in different branches of scientific research.

Sir William was elected an Associate of the Institution in 1881 and a Member in 1891. For several years he served on the Committee of the Irish Centre, of which he was chairman in 1901–02. R. A. H.

CHARLES ORME BASTIAN, eldest son of the late Dr. H. Charlton Bastian, F.R.S., was born in 1869 and died on the 29th October, 1924. Very early in life he developed a taste for mechanical pursuits. He studied at University College, London, and specialized in electrical engineering. On leaving there he was for some time with Messrs. Crompton and Co., Ltd. He was subsequently connected, as a director, with the Bastian Meter Co., Ltd., from the time of the company's formation until he retired in September 1916 in order to devote more attention to the development of his numerous patents, particularly in connection with electric radiators, ovens, water heaters, and the mercury-vapour lamp. He was the inventor of a thermal storage system in which a small electric current is allowed to flow continuously, the hot water being stored in a lagged tank or cylinder. This system was developed in co-operation with Lieut.-Commander F. J. Campbell Allen, of Messrs. Bastian and Allen, and shortly before he died Mr. Bastian was able to see the fruition of his labours in the large water-heating plant which he designed and installed in conjunction with that firm at Wick Lane Baths, Poplar, this plant being claimed to be the first successful one, on a large scale, in this country. He was elected a Member of the Institution in 1903.

F. J. C. A.

HENRY BEVIS was born in 1865 and died on the 16th July, 1925. In 1884 he joined Mr. (now Sir) Hugo Hirst as assistant in the Electrical Apparatus Co., Ltd. In 1886 Mr. Hirst left the firm to join with Mr. G. Byng in forming the General Electric Co., and Mr. Bevis continued to manage the Electrical Apparatus Co. In 1889, however, the company went into liquidation and Mr. Bevis then rejoined Mr. Hirst. He remained with him for 17 years, and in 1907 joined the firm of Pirelli, Ltd., in this country, which was then closely allied with the General Electric Co. He later became managing director of Pirelli, Ltd., and of the Pirelli-General Cable Works, Ltd., and held that position until 2½ years before his death. He took an active part in the inception and formation of the Electrical Trades Benevolent Institution and throughout his life took the keenest interest in its welfare. He was a firm believer in the value of the electrical exhibition and was always a popular and respected figure for his early efforts in this direction. In the early history of the General Electric Co. he made a tour round the world and also visited the Continent and the United States very frequently. In his time he was one of the best-informed men on trade in the electrical industry both at home and abroad. His colleagues and employees will remember him as a man of strong will and a forceful individuality in all matters of business, and they will also remember him as a staunch friend with many endearing and lovable qualities, and as a man with a big heart. He was elected a Member of the Institution in 1901. H. H.

GUSTAVUS FERDINAND BONNOR was born at Highbury on the 17th May, 1868, and was educated first locally and then at Frankfort. He died very suddenly during business hours at Westminster, from heart trouble, on Friday, 6th March, 1925. He served his apprenticeship with Messrs. Gwynne's of Hammersmith, later joining a firm of electrical contractors, whose branch at Bray he managed for some years. He was then appointed electrical engineer to the Bath Corporation, and in 1901 succeeded Mr. C. H. Wordingham as City Electrical Engineer at Manchester. On relinquishing this post he became interested in several mining projects in North Wales, and subsequently became chief engineer of the East Kent Colliery Co. During the war he was engaged on

Government work in connection with the manufacture of munitions. Returning later to consulting work he devoted his energies to research in connection with the production of cement from basic slag, and also designed and superintended the electrical equipment of several large sewage-disposal undertakings. A man of wide experience and great ability in his profession, he was an able mechanic and devoted much of his spare time to model making. Some examples of his skill in this direction have been presented to, and are now on view at, the South Kensington Museum. He joined the Institution as an Associate in 1890, and became a Member in 1897. During the war he changed his name by deed poll from Metzger, adopting that of his mother. F. P.

WILLIAM WALTER BRADFIELD, C.B.E., was the eldest son of William Bradfield, late of the General Post Office, and was born in London on the 18th March, 1879. He received his engineering education at Finsbury Technical College, and in 1897 joined Marconi's Wireless Telegraph Co., Ltd., at that time called The Wireless Telegraph and Signal Co., Ltd., as assistant to Senatore Marconi, and was thus associated with Marconi wireless telegraphy almost from its inception. He was engaged in wireless demonstrations on Salisbury Plain in 1897, and assisted in the erection of the Needles (Isle of Wight) wireless station. In 1898 he conducted a wireless service between Ladywood Cottage, Osborne, and the royal yacht "Osborne," when the late King Edward VII (then Prince of Wales) was confined to the yacht with an injured knee. In the same year Mr. Bradfield installed Marconi apparatus in the first British battleship to be equipped with wireless. He also had charge of a demonstration on board the U.S.A. battleship "Massachusetts." In the following year he assisted in the installation of Marconi wireless apparatus on the Borkum Riff light vessel and Borkum lighthouse. In 1901 he had charge of a demonstration for the French Government, of wireless working between Calvi (Corsica) and Antibes in the French Riviera. He was also responsible for the installation of the famous wireless stations at Siasconset (Nantucket Island) and on the Nantucket light vessel. Mr. Bradfield was appointed chief engineer of the Marconi Wireless Telegraph Co. of America in 1902. During his tenure of this office he attended the second International Radio Telegraphic Conference which met in Berlin in 1906. He returned to England in 1908 as deputy manager of Marconi's Wireless Telegraph Co., Ltd., and of the Marconi International Marine Communication Co., Ltd., and in 1910 became manager of both companies. In 1917 he was elected to the board of directors of both companies. During the war he devoted his entire energies to the support which the Marconi companies gave to the Services, and it was for this war service that he was appointed a Commander of the Order of the British Empire. For over a quarter of a century he was concerned with the development of wireless, particularly in connection with shipping, and it may be fairly stated that he was largely responsible for the efficiency of maritime wireless services and the high standard which they have now reached. In both business and social life he revealed a character which gained for him innumerable friends. His delightful personality endeared him to both business friends and colleagues, and his death leaves a sense of more than usual loss in those with whom he was associated. He was elected a Student of the Institution in 1897, and a Member in 1920. He was also a Fellow of the Institute of Radio Engineers (America), and an Associate of the American Institute of Electrical Engineers. He had been in failing health for some time before his death, but could not be persuaded to leave his work until the end of 1924, when he went to Switzerland for treatment; it was, however, too late, and he returned to London, where he died on the 17th March, 1925. A. G.

JOHN DANIEL LOVE BRADWELL was born on the 29th March, 1878, at Ashton, Lancashire, and died on the 19th August, 1925, at Solihull, near Birmingham. He was educated at Malvern College and Lausanne, Switzerland, and afterwards studied engineering at King's College, London, from 1896 to 1899. From there he went to Messrs. Ferranti, Ltd., as a pupil for two years, and stayed on with that firm for a further two years in their experimental department. He then obtained, in 1903, an appointment with Messrs. Willans and Robinson, Ltd., at Rugby, and was in charge of the electrical department of their testing shop. In November 1905 he left Rugby at the same time as Mr. E. A. Reynolds, who was also in the testing shop at Messrs. Willans and Robinson, and they commenced business at Birmingham in partnership, under the name of Reynolds and Bradwell, as electrical contractors specializing in factory equipment. He remained a partner in that firm until his death. In 1918 he was elected to the Council of the Electrical Contractors' Association, but had to retire soon after owing to ill-health, and subsequently was unable to take much active interest in business. He joined the Institution in 1903 as an Associate and was elected a Member in 1913. E. A. R.

ELLIS HERBERT CRAPPER, M.Eng., was born in Sheffield on the 24th June, 1861, and died at Rhos-on-Sea on the 22nd March, 1925, during a temporary absence from his home. He leaves a widow and one daughter. He received his early education at the Central School, Sheffield, and later was a student under Dr. Hicks, F.R.S., at the Firth College (now absorbed in the University of Sheffield). He also attended some of the special summer courses at the Royal College of Science, London. The whole of his subsequent career was spent in his native city. In early life he was a teacher at the Philadelphia Board School, from which he rose to the position of Peripatetic Science Master under the old School Board. At the end of the year 1889 he was appointed assistant master in the Junior Department of the Technical School (now absorbed in the University of Sheffield). Three years later he was transferred to the Senior Department, as Lecturer in Mathematics and Physics, and after the lapse of about another year he became Lecturer in

Physics and Electrical Engineering. On the formation of the University College he was appointed Lecturer in Electrical Engineering, and when the University was established in 1905 he became Senior Lecturer in Electrical Engineering, a post which he held for about 12 years, during which period the best part of his scholastic work was accomplished. In February 1917 his position was changed to that of Independent Lecturer in charge of the Electrical Engineering Department, a position which he occupied at the time of his death. He thus devoted the whole of his life to the cause of education, a pursuit which fitted him perfectly, and by his death in his sixty-fourth year the University, and especially the Applied Science Department, has sustained a very real loss. Not only was he a man of considerable attainment, a hard worker, unsparing of himself in lecture room and laboratory alike, but he possessed a genial and kindly personality, and was held in high esteem by both staff and students.

He was the author of the following books: "Electric and Magnetic Circuits," "Practical Electrical Measurements," "Arithmetic of Electrical Engineering," "Arithmetic of Alternating Currents," "Electric Circuit Problems"; and in addition he contributed numerous articles over a long period to the engineering journals. He made the testing of magnetic material his particular study, and during the war period was engaged in important magnetic tests in connection with magneto magnets and special nickel steels for the Aeronautical Inspection Department. Last year he wrote a series of articles entitled "The Elements of Magnetic Analysis," which appeared in *Engineering* and evoked favourable comment both at home and especially in the U.S.A. Many of the Sheffield steelworks, and also officials of the Indian Government, have sought his advice on the choice and testing of magnetic materials for special purposes. Apart from his scholastic attainments, he was a well-known figure in local Freemason circles, a Past Master of the St. Leonard's Lodge, and one of the founders of the University Lodge.

He was elected an Associate of the Institution in 1894, was transferred to Associate Membership in 1899, and became a Member in 1900. He was instrumental in the formation of what is now the Sheffield Sub-Centre and the Sheffield Students' Section.

C. H. H.

JAMES HUNTER GRAY, K.C., M.A., B.Sc., died unexpectedly after a relatively short illness on the 1st June, 1925. By his death the electrical industry especially, and industry in general, have lost one who was most enthusiastic in promoting development and progress, and in the exercise of his profession as a patent barrister his sympathies and efforts were ever in this direction. Born at Midcalder, Midlothian, on the 3rd September, 1867, he went at an early age to George Watson's College, Edinburgh; and on completing a successful school career he chose the scientific profession. He elected to study under the late Prof. Blyth, LL.D., of Anderson's College, Glasgow, a physicist and electrician of a high order and a model teacher. Mr. Hunter Gray, while specializing in mathematics and physics, educated himself in other directions in order that he might qualify himself for the degree of Bachelor of Science in London University. Part of this education was obtained as a summer-session student at Edinburgh University, and the remainder by home study and at Anderson's College.

After graduating at London University Prof. Blyth introduced him to Lord Kelvin, then Sir William Thomson, who admitted him to the physical laboratory in Glasgow University as a research student. While devoting the main part of his time to research and the study of higher mathematics and physics, Mr. Hunter Gray attended the usual Arts classes and graduated Master of Arts in the University, at the same time carrying on his research work in the laboratory. The results of some of this work were published in the proceedings of scientific societies and it may be useful to mention three * of these, as they are of interest to engineers. The first-mentioned is of special interest to electrical engineers concerned with wireless.

In 1891, the 1851 Exhibition Scholarships were instituted and Mr. Hunter Gray was nominated by Lord Kelvin as the University of Glasgow Scholar. The above-mentioned researches were carried out during the tenure of his Exhibition Scholarship. Towards the end of this period the well-known cordite patent action of Nobel *v.* Anderson was started and Dr. Bottomley (Lord Kelvin's nephew), who was retained by Nobels as a scientific witness, asked Mr. Hunter Gray to assist him with the experimental work on the case. He was thus brought into contact with Fletcher Moulton and other men then prominent at the English Bar. This case decided him to adopt the career in which he became so eminent. Not content with eating his dinners and studying law for his Bar examinations, he gained considerable knowledge of the practice of the law as a pupil in the office of a prominent firm of London solicitors before he was called to the Bar in 1895.

He was elected an Associate of the Institution in 1899 and became a Member in 1919. He served on the Council from 1915 to 1918, and his services were at all times freely available to the Institution. In this connection he served on several of its Committees, including that under Mr. Mordey on the 1919 Patents Act, where the assistance that he gave was most valuable. His work whether on committee or otherwise was most enthusiastically and unostentatiously done.

There are few patent actions reported during the last 25 years in which he was not prominent. It may be said that there was not a single action relating to electrical patents in which he did not appear as counsel and mostly in favour of the patentee. In addition, he acted for the Crown on many occasions on electrical accident inquiries, in cases under the Royal Commission on Awards to Inventors, sometimes for, and sometimes against, the Crown. He was intensely interested in his profession and in the technical subjects with which he had to deal. He took infinite pains to understand his case, and he was incapable of taking in argument

* J. HUNTER GRAY: "Slow Oscillations produced on discharging Electric Condensers of Great Capacity," *Report of the British Association for the Advancement of Science, Edinburgh*, 1892.

J. HUNTER GRAY and J. B. HENDERSON: "The Effects of Mechanical Stress on the Electrical Resistance of Metals," *Proceedings of the Royal Society*, 1893.

J. HUNTER GRAY: "On a Method for determining the Thermal Conductivity of Metals, with applications to Copper, Silver, Gold and Platinum," *Proceedings of the Royal Society*, 1894.

what he considered to be a bad point. In his conduct of a case, whether as examiner or cross-examiner, he always followed a definite line which he had planned beforehand so as to develop his case as shortly as possible, and in summing up he was brief and concise, in many cases too brief to satisfy the eager client, but more often than otherwise he achieved the result that he and the client desired.

Mr. Hunter Gray, or "Jimmy" as his many friends and intimates called him, was not only eminent and popular in his profession but his lovable disposition and character endeared him to all with whom he came in contact. One cannot better the estimate of the impression which he made on his fellows than that which is contained in the following extract from the beautiful tribute to his memory by Lord Hewart, the Lord Chief Justice, in *The Times* of the 6th June:—"But if 'Jimmy' had a genius for law and a genius for advocacy, he had also something far more important than either or both—a genius for friendship. No man was ever more beloved by those who knew him. He had not one enemy. While there was nobody who spoke, or had occasion to speak, one word against him, his praises were on all men's lips, as they are to-day when we miss him and deplore his loss—the staunchness and tenderness of his friendship; the complete lovableness and simplicity of his character; the playfulness and humour which, while they revealed the heart of a child, drew all children to him; the unselfishness and generosity which were not so much characteristics of his life as the very essence of his life itself."

OLIVER HEAVISIDE, F.R.S., the first Faraday Medallist of the Institution, was an eccentric genius, such as occur from time to time in the history of science and the arts, one of those who seem to have a native faculty either of understanding recondite matters or of doing things which to ordinary people are inexplicable, and yet who find it difficult to mix with their fellows, and have less than a competent grip on the ordinary affairs of life. Puzzling psychical problems are not unknown. An infant prodigy presents a problem not easy of solution. A child is sometimes found who can play a musical instrument without having gone through the drudgery of learning, or who has an innate faculty for arithmetical calculation. We can hardly tell whence such a faculty arises, nor what may be its result. That Oliver Heaviside was a prodigy of this class there is no evidence to show. Details of his youth are unknown to the public. He would seem to have been an ordinary telegraph operator when first known, but one who developed a surprising mathematical faculty without apparently adequate cause and to whom the details of recondite electrical theory seemed simple and obvious. He had not the advantages—or, as he might have said, the disadvantages—of a Cambridge training; and his mathematics were not of the Cambridge type. It may be that they were more of the German type; but there is no reason to suppose that he learnt them in Germany, nor is it easy to say where he learnt them. His treatment of science had idiosyncrasies of its own; and he seemed to know intuitively what most able people have to spend years in learning. The result was that for some time his writings were difficult to read and were for the most part unappreciated by orthodox mathematicians; whilst to many electricians they seemed in the clouds, with no likelihood of practical application to the affairs of earth.

He is not to be put on a level with Clerk Maxwell, who grasped the experimental facts discovered by Faraday and threw them into mathematical form so as to deduce from them by regular process their intimate meaning and vital and important consequences. He was rather one who absorbed the views of Clerk Maxwell, apparently without effort, and applied them in his own way with further elaboration and results. In the "Electrical Papers," which for many years were published in the *Electrician* and were collected in two volumes under that title, he covered a great part of electrical science after his own manner; and in his subsequently-produced three volumes on "Electromagnetic Theory" he collected those which had a special bearing on telegraphy in its widest sense, and developed them with special attention to the new theory of electric waves.

Everything that concerned the interaction of ether and matter must have had a fascination for him. He absorbed (after his own fashion) the essence of Poynting's theorem about the way in which electric and magnetic fields were interlocked, and how their interaction inevitably resulted in locomotion—whether the free locomotion of something with the speed of light, which we are familiar with as radiation without exactly knowing what it consists of, or the more constrained locomotion of matter under electromagnetic influence, which is equally familiar in dynamos and electric motors. He knew no more than the rest of us what the etheric modifications called an electric field, on the one hand, and a magnetic field, on the other, really consist of; but he recognized an electric charge as a peculiar modification of the ether, and devoted himself to the problem of what happens when an electric charge is made to move, thereby developing or exhibiting magnetic effects.

A great part of the theory of electric waves was elaborated in more orthodox fashion by Hertz; but Heaviside pursued the subject into remarkable detail, and recognized that these waves constituted the foundation for electric telegraphy of all kinds. He drew no distinction of a fundamental kind between radio telegraphy in free space and the other kind which is guided by conductors: to him the processes were fundamentally the same, and only modified by artificial arrangements and special constructions. He thus approached telegraphy from what may be called the "wave" end, emphasizing from the beginning the vital importance of what was known as self-induction; he elaborated the influence of the two great and still unknown etherial constants, and he thus gave the theory of telegraphy in its most general and comprehensive form.

To enter into a little more detail. The achievement which first brought him into effective notice was the fact that he extended and supplemented Lord Kelvin's original theory of cable telegraphy (which so far had

been conducted on the lines of Fourier's theory of the conduction of heat), by introducing the factor of inductance or self-induction, which up to that time, so far as it has been attended to at all, was regarded by practical telegraphists as a bugbear or a nuisance to be got rid of or eliminated as far as possible. He showed that Lord Kelvin's diffusion theory was very incomplete, and that by attention to the ignored factor it might be possible to attain much better results. In fact he gave the complete theory of cable and all other telegraphy, showing that in every case it depended on waves travelling through the ether, which were guided but at the same time modified, smoothed out, attenuated and distorted by material substances, especially by the conductors which were used to guide them to their destination. Fortunately, Lord Kelvin—though he never apprehended electric waves to their full extent and was doubtful about many points in Clerk Maxwell's theory—was able to recognize that his diffusion theory was incomplete and that Heaviside had made a great step in advance. He recognized fully that Heaviside's theory of cable signalling was more complete than his own; and his recognition did much to introduce Heaviside to the knowledge of the wider electric world.

Before that time only a few—such as FitzGerald and Lodge and Searle and Perry—had seen any possible useful meaning in Heaviside's rather eccentric lucubrations, Perry having been attracted to them by the ingenuity of some fractional differential operators like $\sqrt{(d/dt)}$ which were known to pure mathematicians like Henrici but which had not been applied to physical problems. But Heaviside's ambition was that his work should be recognized not merely by mathematicians, with whom he probably felt himself on equal terms, but by practical telegraphists; for he saw that his mode of regarding the facts, and his completer theory, must in the long run have a revolutionary effect on telegraphic and especially telephonic transmission. So he was bitterly disappointed when British telegraphic authorities, headed by Sir William Preece, who regarded his notions as absurd, caused his papers and those of his brother A. W. Heaviside—who, still engaged in northern telegraphic enterprise, sought to put them into concrete and practical form—to be rejected by the Society of Telegraph Engineers. For what he regarded as the ridicule thus cast upon his work by practical men he never forgave Sir William Preece, and throughout his subsequent writings there occur sarcastic references to those in authority who were unable to recognize the truth of what specially concerned their art. He even managed to introduce these sarcasms, in a veiled form—so veiled as to seem inoffensive and probably unintelligible to the editor and other readers—into the concluding portion of his article on the "Theory of Telegraphy" in the tenth or supplementary edition of the "Encyclopædia Britannica."

That Heaviside's theory has now been applied on an extensive scale both to sea and land telegraphy and telephony—especially perhaps in the United States under the auspices of the Western and the General Electric Companies—we all know. Among the first to take the theory up and seek to make it practical was Silvanus Thompson in this country and, with considerable success, Dr. Pupin in America. The main feature is the purposed introduction of that bugbear of old telegraphists, self-induction, in order to give momentum to the waves and thus counter the deleterious influence of resistance and capacity. Heaviside knew well enough that if the dissipation of energy by metallic resistance could be abolished, transmission would be easy and distortion reduced to zero. That is what constitutes the great advantage of radio or wireless telegraphy: the waves are there travelling in a perfectly transparent medium, without resistance or absorption of energy, nothing but mere attenuation with distance; and accordingly every feature of the wave is preserved, so that they arrive just as they were sent, waves of all lengths travelling with the same speed, and the shape or features of the waves are maintained intact, as good as new, even though the amplitude or energy might be reduced to a millionth or a billionth of what it was at the start. The essence of the problem is that the electric and magnetic energies must be maintained equal, as the essential condition for a true wave. Any absorption of current or magnetic energy, leaving one factor stronger than the other, would begin to reflect part of the wave back upon itself, would cause different harmonics to go at different rates, and the features would accordingly be smoothed out, as a coach spring smoothes out the irregularities of a road. Elasticity and friction were the deleterious elements: momentum is needed to counteract them; and this momentum, which in the ether is of a magnetic character, could be provided in cases where resistance and capacity were inevitable, by the introduction of induction coils at short enough intervals, or by the continuous increase of inductance, as by coating a copper conductor with a sufficiently permeable coat of special quality iron. In that way the lost magnetic energy could be replaced, and the two energies still kept more nearly equal.

The writer has dealt at some length with this matter, which doubtless is now fairly familiar to electrical engineers, because of its practical interest and importance; but the theory of electrical waves, as given especially in Heaviside's third volume, may ultimately turn out to have features of still more absorbing interest. It is too soon as yet to realize the bearing of his writings on the theory of the ether, a theory to which Sir Joseph Larmor, Lord Kelvin and G. F. FitzGerald have in their own way so powerfully contributed, and which has since been extended by Planck and Einstein and Eddington and Jeans, without (in some cases) explicit recognition of what the ultimate bearing of their theories will be. Meanwhile that article in the "Encyclopædia Britannica" above referred to, which is reproduced in Heaviside's third volume of "Electromagnetic Theory," is a wonderful summary of electromagnetic doctrine; a little puzzling in places, as usual, because of his mode of expression, but exhibiting a comprehensive grasp of the main features of the problem, and a clear statement of what is at present known, such as few others would have been able to put in so small a compass.

Not only in this country but rather specially on the Continent and in America has Heaviside's work been appreciated, and even his reformed nomenclature often adopted. For instance, Professor H. A. Lorentz in his admirable lectures in 1906 on "The Theory of Electrons" (published in this country in 1909) says concerning Maxwell's equations: "We shall not use these formulæ in the rather complicated form in which they can be found in Maxwell's treatise, but in the clearer and more condensed form that has been given them by Heaviside and Hertz." Then he goes on to approve Heaviside's crusade against what he called the eruption of 4π's, due to the original statement by Coulomb of the force between two charges, with r^2 in the denominator instead of $4\pi r^2$—which would have been better, since e and m would have then given the total number of lines of force, instead of the lines through unit angle; and 4π would have been eliminated from a great number of equations if it had been introduced in its simple and natural place. So Lorentz goes on: "In order to simplify matters as much as possible, I shall further introduce units of such a kind that we get rid of the larger part of such factors as 4π and $1/(4\pi)$, by which the formulæ were originally encumbered. As you well know, it was Heaviside who most strongly advocated the banishing of these superfluous factors, and it will be well, I think, to follow his advice." This may seem a small matter, but a practical appreciation by so great a man as Prof. Lorentz could not fail to be gratifying, and is typical of the widespread recognition of Heaviside's work, which, delayed through many impecunious years, did ultimately begin during the later portion of his life.

The facts of Oliver Heaviside's life have been recorded elsewhere, and may here be reproduced as this is an obituary notice. The writer's own personal appreciation of him will be found in the *Electrician* (1925, vol. 94, p. 174), and on page 186 of the same number will be found a portrait, the only one known to exist.

Concerning his work as a young man, Mr. W. Brown writes as follows: "As a junior telegraph clerk I worked with Mr. O. Heaviside in 1868. He was then a young man and was employed by the Danish Cable Co. (the Great Northern Telegraph Co.) as telegraphist. The cable was terminated in, and operated from, the office of the United Kingdom Telegraph Co.—the pioneer of the shilling rate—in Queen-street, Quayside, Newcastle-on-Tyne. Wheatstone apparatus was used, and it was on that circuit, Newcastle-on-Tyne to Jutland, where I made my first acquaintance with that system. Oliver Heaviside was the principal operator at Newcastle—appointed no doubt by the influence of his uncle, Sir Charles Wheatstone. He was usually on day duty. He was a very gentlemanly-looking young man, always well dressed, of slim build, fair hair, and ruddy complexion. I think he was there until the transfer, after which the cable company rented a room adjoining those occupied by the Post Office, wherein the combined plant of the acquired companies was concentrated. The cable telegrams were then passed through a hatch in the doorway separating the premises and the staffs, and from that time I lost sight of Oliver Heaviside. My next recollection of him was when he emerged as a mathematician."

The following biographical facts are taken from portions of an excellent obituary notice in *Nature* of February 14th, 1925, by Dr. Alexander Russell:

"Heaviside was born in London on May 13, 1850. After leaving school he obtained a post with the Great Northern Telegraph Co. at Newcastle-on-Tyne, which he held for several years. During this period he communicated papers to the *English Mechanic*, the *Telegraphic Journal* and the *Philosophical Magazine*. These papers are of more than average ability and show great promise. For example, in 1873 he showed that quadruplex telegraphy was a possibility. He published many papers, which gradually became more and more technical and more and more difficult to understand, as it became necessary, in order to avoid repetition, to assume that the reader knew some of the writer's previous work. Consequently he had difficulty in getting them published in the ordinary technical journals. He had, moreover, to run the gauntlet of a good deal of unintelligent criticism, and none of his discoveries received that immediate recognition which their merit deserved. Heaviside communicated to the Society of Telegraph Engineers (now the Institution of Electrical Engineers) a paper solving the problem of the electrostatic and electromagnetic interference between overhead parallel wires, a problem which has come to the front at the present time. His methods of measuring mutual inductance, published in 1887, are of great value in themselves, and, like most of Heaviside's work, have been most fruitful in suggesting extensions to others. He was the first to solve the problem of the high-frequency resistance and inductance of a concentric main. It would probably have remained neglected for many years had not Kelvin given some of his results in his presidential address to the Institution of Electrical Engineers in 1889. From the practical point of view, Heaviside's most important work was laying the foundation of the modern theory of telephonic transmission. His theory of the distortionless circuit showed clearly the lines on which telephony could be developed. Working on these lines some ten years later, Prof. Michael Pupin in the United States developed his loading coils, and long-distance telephony was born. In 1891 Heaviside was elected a Fellow of the Royal Society. In 1892 his earlier 'Electrical Papers' were published in two volumes. The value of his work began then to be realized by electricians. He did perhaps more than any man to show the value of a knowledge of physics and of mathematical theory in the electrical industry. Pupin has said that Heaviside did much 'to introduce the living language of physics in place of the sign language of mathematical analysis.' The first volume of Heaviside's great work on 'Electromagnetic Theory' was published in 1893 and the second in 1899. His original intention was to publish the third volume in 1904 and the concluding volume in 1910, but this he found impossible, and so published the third and concluding volume in 1912. Heaviside was the first to give the theory of the steady rectilinear motion of an electron through

the ether, a theory which has been developed by others—notably by Searle—with important results. He was one of the first to predict the increase of mass of a moving charge when its speed becomes very great. To verify all Heaviside's reasoning, and especially to examine the validity of some of his mathematical methods, will provide work for many mathematicians and physicists. Many theorems given in his article on the 'Theory of the Electric Telegraph' in the "Encyclopædia Britannica" are constantly quoted by the writers of textbooks. In particular his description of what is now called the 'Heaviside layer,' by means of which Hertzian waves are supposed to be bent round the earth, is familiar to every radio engineer. In the later years of his life Heaviside was one whom every electrical engineer delighted to honour. In 1908 he was elected an Honorary Member of the Institution of Electrical Engineers. When in 1921 the Faraday Medal was founded, it was universally considered most appropriate that Heaviside should be the first Faraday medallist. The president, Mr. J. S. Highfield, went to Torquay and presented it to him in person. He was an honorary Ph.D. of Göttingen, an honorary member of the Literary and Philosophical Society of Manchester and of the American Academy of Arts and Sciences. For fifty years Heaviside lived practically a hermit's life in Devon. He was a good correspondent, but very difficult to approach personally. In his later years Dr. and Mrs. Searle, of Cambridge, were practically his only friends. The Government gave him a Civil List pension, and about twenty years ago Mr. Asquith increased it. The Institution of Electrical Engineers took a filial interest in him, and it is gratifying to remember that during the last few years of his life the Institution kept in constant touch with him. In the preface to his 'Electrical Papers' he says that the question 'Will it pay?' never interested him. He died at Torquay on Tuesday, February 3 (1925), and was buried on Friday, February 6, in the same grave as his father and mother; only relatives, and Mr. R. H. Tree representing the Institution of Electrical Engineers, being present. Thus ended the life of one who has left a record of work which has proved of great value to the world."

O. L.

ARTHUR JACOB died at his home at Hatch End, Middlesex, on the 3rd April, 1925, at the age of 57 years. He was the son of Archibald Hamilton Jacob, aurist, of Dublin, and received his technical education at the Royal College of Science, Dublin. His early experience was gained under Dr. S. Z. de Ferranti, then engineer-in-chief of the London Electric Supply Corporation, Ltd.—the first company in London to undertake the supply of electricity for lighting and power purposes. Mr. Jacob was assistant engineer with this company for five years, having successively charge of their mains, substations and Deptford power station; this plant, as is well known, was at the time an unique example of the possibilities of economic power distribution by the use of large units (1 500 h.p.) and high pressure (10 000 volts). Mr. Jacob's later experience included the position of resident engineer to the Electricity Supply Co. for Spain, Ltd., at Madrid. Subsequently, as chief resident engineer to the British Thomson-Houston Co., Ltd., he was responsible for the conversion of the entire Dublin United Tramways system from horse to electric traction, the contract including the erection of two power stations and substations for the supply of polyphase and direct current for the operation of 300 cars on 42 miles of track. On completion, Mr. Jacob operated this system for a period of three months before handing over. Later, as general manager of the British Schuckert Electric Co., he was responsible for traction, power and lighting schemes for the Corporations of Paisley, Coventry, Southampton and Birmingham, respectively, as well as for the Dunlop Rubber Co. and numerous other municipal and private undertakings. On the acquisition of the British Schuckert Electric Co. by Siemens-Schuckertwerke, Berlin, Mr. Jacob joined Siemens Brothers and Co., Ltd., and upon the formation by that company of Siemens Brothers Dynamo Works, Ltd., undertook the management of the latter company's central station department. In January 1908 he became a member of the management of the British Aluminium Co., Ltd., aluminium producers, and until the time of his death was charged with the development of the use of aluminium for industrial purposes in general, and electrical purposes in particular; in later years he also directed certain of the company's subsidiary undertakings. Mr. Jacob was a member of the Overhead Transmission Line Materials Committee of the British Engineering Standards Association; also a member of the Overhead Wires Committee of the British Electrical and Allied Industries Research Association. In addition to being a Member of the Institution he was a member of the American Institute of Electrical Engineers and the American Electrochemical Society, an original member of the Institute of Metals, and a member of Executive of the Federation of British Industries, the British Engineers' Association, the Industrial League and Council and other organizations. To his colleagues, as well as to a large circle of friends and acquaintances in this and other countries, the untimely death of Mr. Jacob brought a distinct sense of loss. A man of no mean powers, he combined with these a soundness of character, an attractive personality, warm sympathies and a ready wit, establishing in the course of years an extensive personal connection in the engineering industries. He was elected a Member of the Institution in 1901.

W. M. Mn.

WALTER LANGDON-DAVIES died in December 1924 at the age of 57 after a long and painful illness. Although his life cannot be described as one of material success, yet there are not a few in the electrical world who will recall him for many years to come as an active and eager pioneer who broke new ground, occasionally for his own purposes, but more often to clear the path for others. He received his scientific education at the School of Mines, now the Royal College of Science, at South Kensington. His first work was under his father, Charles Langdon-Davies, who was at that time developing the phonopore, a telegraphic system

of the von Rysselberg period. While engaged on this he devised the induction motor, which was later brought out by a company bearing his name. For some years he was the technical director of this company. Afterwards he went to Vancouver, where he worked as a consultant with the great power distribution company of British Columbia. On his return to England he devoted himself to electric welding, and the Daysohms Welding Co. was formed to develop his inventions. With this company he was connected until his death. So bald a record of his activities must seem to those who knew him an inadequate reflection of the absorbing passion for electrical discovery which animated him almost to the exclusion of any other interest. Nor was his method of research that which is in favour at universities and places where they proceed by careful induction. "With him it was always instinct," writes a friend, "and instinct nearly always right; then experimental proof; then theory; and, last and least, reward. He had more scientific curiosity and enthusiasm than anyone I ever knew." It was as he lay in the last few months on his bed of pain that he formed the determination to leave his body, racked as it was with cancer, for purposes of research, and the present writer recalls the enthusiasm with which he said one day that this was the future life to which he looked forward and, since otherwise he was now useless, the sooner the new life began the better. He was elected a Member of the Institution in 1919.

B. N. L.-D.

ANDREW BRUCE MACLEAN was born in Glasgow in 1856 and died on the 17th May, 1925. Educated in Glasgow, he left school early to take up a career of commerce. While still a boy he joined the Glasgow agency of the India Rubber, Gutta Percha and Telegraph Works Co., Ltd. (the Silvertown Company), then under the management of the late Mr. Matthew Gray. His business aptitude and alertness were quickly recognized by Mr. Gray, and rapid promotion followed. While still in his early twenties he was appointed to the Silvertown agency in Sheffield; this was followed a few years later by the similar post in Birmingham, and in 1890 he returned to Glasgow to take charge of the Silvertown agency in his native city. He continued with the company until 1897, when he founded the Craigpark Co., Ltd. Five years later the need for expansion of premises, and of the business generally, called for further capital. A suitable factory was found in Springburn, and the new company, the Craigpark Electric Cable Co., Ltd., of which he was managing director until his death, absorbed the original company. His tireless energy, fearlessness, grasp of detail and an unusually quick and active mind soon led the company through the troubled waters of its early years. The electrical trade loses one of its oldest members; probably no one at the present time can claim to have been in the trade for 54 years. In Scotland at any rate he was, from the commercial point of view, a real pioneer, and he was probably the first to attempt to sell telephones for use in offices and factories, and this at a time when exchanges had not been thought of. His geniality and kindliness endeared him to a large circle of friends, who were quick to appreciate his sterling qualities of heart and mind. He was elected a Member of the Institution in 1904.

M. M.

WILLIAM LEONARD MADGEN died in January 1925 at the age of 63 years. He was a pupil in the School of Electrical Engineering, Hanover-square. He then joined the Telephone Company, and in 1882 went to Belfast as district manager; a little later he joined Woodhouse and Rawson as one of their departmental managers. Between 1888 and 1891 he was associated with Mr. Manville (now Sir Edward Manville) and with Mr. Statter. In 1892 he co-operated with the late Robert Hammond in establishing the journal *Lightning* (now the *Electrical Times*). In 1893 he was engaged in developing the Ferranti meter business. During the next three years he was occupied with propaganda relating to the maximum demand system of charging for electricity, introduced by Mr. Arthur Wright. In 1896 he did important work in connection with the formation of the Municipal Electrical Association. He and the writer thus approached the development of the electrical industry from opposite poles. He was at first a strong advocate of municipal trading; but he changed his views, notwithstanding his close association with municipal authorities, and became a supporter of the Industrial Freedom League, formed to show the unwisdom of developing the electrical industry on parochial lines. In 1900 he was busy promoting electrical power Acts; his paper and the discussions before the Institution on this subject, published in the *Journal*, constitute interesting landmarks in the development of the industry. When in 1897 the Electrical Power Distribution Co. was formed, no outside capital could be raised for the enterprise; for even the writer's financial group regarded it as too speculative. The pioneering work of this company required several years of hard work without profit; some time later the British Electric Traction Co. absorbed the E.P.D. Company, and Mr. Magden became a director of the B.E.T. Company. His ideas of business were tempered by social views prompted by genuine, not political, desire to ameliorate the conditions of the masses, as is shown by his paper on "Industrial Distribution: the Crux of the Overcrowding Question" (*Journal of the Royal Society of Arts*, 1902). In his schemes he aimed at symmetry and completeness not generally attainable. This is seen in the titles he adopted. For instance, a little lighting company for Lewes was called the County of Sussex Company. He had a friendly emotional disposition, with a keen sense of justice. He could easily forget as well as forgive unintentional injuries, but he would never forgive the sins of insincerity. Unfortunately, he did not sufficiently organize his activities on matters outside business to obtain the diversion which intense application to responsible work required. He was elected an Associate of the Institution in 1881, and a Member in 1890.

E. G.

WALTER MARKBY was born in London in 1865 and died suddenly from heart failure at his home in

Paddington on the 29th November, 1924. He was apprenticed at the North London Railway Works, going through the fitting shop and drawing office, and went direct from there, in June 1890, to the Metropolitan Electric Supply Co. under Mr. Frank Bailey. He remained all his life in the service of this company. Starting in the drawing office, he transferred as an engineer in charge of the old underground generating station at Whitehall to Manchester-square station in 1892. In 1893 he became superintendent engineer at Whitehall Court and in 1894 superintendent at the company's Amberley-road station, being in 1902 transferred to the main generating station at Willesden as superintendent and, upon the retirement of Mr. J. S. Highfield in 1916, was appointed chief engineer of the company, which position he held to within a few months of his death. Owing to an accident when very young, he was rendered permanently lame. He was a man of very retiring disposition, whose every effort was centred in his work; consequently he was not very well known to the electrical profession. That he was extremely kindhearted and greatly esteemed by his employees was evinced by the fact that every man who could be spared attended the memorial service held in St. Saviour's Church, Paddington, upon the occasion of his funeral. He was elected an Associate of the Institution in 1891, an Associate Member in 1899, and Member in 1905. A. F. H.

THOMAS COMMERFORD MARTIN was born in London in 1856 and when quite young went to America, where from 1877 to 1879 he was associated with Edison in electrical development. In 1883 he was appointed editor of the *Electrical World* and held that position for seven years, resigning to assume the editorship of the *Electrical Engineer*. In 1899, when the *Electrical World* came under the control of the McGraw-Hill Publishing Co., which also purchased the *Electrical Engineer* and amalgamated the two papers, Mr. Martin again became editor of the *Electrical World*, holding this post until 1909. In addition to contributing on electrical subjects to periodicals, he wrote a number of books, amongst these being "The Electric Motor and its Applications," "Inventions, Researches and Writings of Nikola Tesla," "Edison—His Life and Inventions" (in collaboration with Mr. F. L. Dyer), and "The Story of Electricity" (in collaboration with Mr. S. L. Coles). Mr. Martin was elected a Foreign Member of the Institution in 1891 and a Member in 1911. He served as President of the American Institute of Electrical Engineers in 1887 and as executive Secretary of the National Electric Light Association from 1910 to 1919. He died on the 17th May, 1924, at the age of 67.

HARRY BRYANT MATTHEWS was born in 1876. His engineering training was acquired partly in works, and partly in university classes. He attended as a full-time student at two universities, but did not in either case fulfil all the conditions necessary for gaining a degree or diploma. His technical training was, nevertheless, most thorough. He spent two years—1902 and 1903—at the Birmingham University as a research scholar, after winning in open competition the Bowen Research Scholarship. During those two years he devoted a good deal of time to research work on single-phase motors. In September 1903 he was appointed senior lecturer in electrical engineering at the Birmingham Technical School, and remained on the staff there for nine years. He was an able and efficient teacher and showed much initiative in devising new and valuable laboratory arrangements by means of which large evening laboratory classes of an advanced grade could be efficiently dealt with. He was very fond of teaching, was always kindly and sympathetic with his students, and proved to be a most successful head of an electrical engineering department. He was enthusiastic, and had many other attractive social characteristics which caused him to be much liked by all who came in contact with him.

He was elected an Associate Member of the Institution in 1905 and a Member in 1913, and took an active part in the discussions of the Birmingham Local Section, now South Midland Centre, but he had little ambition to write formal papers describing his own experimental work. His chief contribution is to be found in Volume 40 of the *Journal*, and describes some of the results which he obtained on the distribution of magnetic flux in the air-gaps of machines having slotted armatures. He acted as Honorary Secretary of the Birmingham Local Section from 1906 until he left for India in 1912. He did excellent work for the Institution in this capacity, and was highly esteemed by his fellow members.

He took a great interest in the Territorial movement. In 1908 he energetically assisted in raising the Telegraph Companies of the Southern Command. He held the rank of Captain of the Wireless Section, and was the first officer serving in that capacity in the Midlands. His extensive personal acquaintance with young electrical engineers, due to his two positions as a teacher in the Technical School and as Honorary Secretary of the Local Section of the Institution, enabled him to exert considerable influence in recruiting for the Corps in the days shortly before the war. In 1912 he was offered, and accepted, the post of Assistant Professor of Electro-technology at the Indian Engineering Research College, Bangalore. Later he became Professor of Electrical Engineering at the College of Engineering, Guindy, Madras. He returned to this country in February 1921 on medical leave, owing to a nervous breakdown brought on by overwork, and did not recover sufficiently to take up his work again. He died in the summer of 1925. W. E. S.

ALFRED ERNEST MILLS, M.A., died on the 15th August at North Finchley at the age of 61. He was educated at University College School, London, and Clare College, Cambridge. Owing to ill-health he did not follow an active engineering career but always took a great interest in the progress and development of the science. In 1887 he was appointed Assistant Secretary to the Railway Benevolent Institution, and in 1898 became General Secretary. He held that position for 27 years, eventually retiring at the end of 1924 owing to failing health. He was elected an Associate of the Institution in 1885 and a Member in

1887, and was also a Fellow of the Physical Society of London. G. M.

JAMES PIGG died on the 8th July, 1925, aged 68 years, after a few days' illness and an unsuccessful operation. He joined the Institution as an Associate in 1893, became an Associate Member in 1899, and a Member in 1907. His association with electrical work began with some of the earliest applications of electricity when, as a boy, he started work in the signals department of the Stockton and Darlington Railway. By steady application he rose to the position of inspector of a district, obtaining the elements of his theoretical training by evening study at the Durham College of Science, now Armstrong College, Newcastle-on-Tyne. After the amalgamation which formed the North-Eastern Railway, when the company began, in 1891, to introduce electric lighting and power, he was selected to supervise the work. He was intimately connected with all electrical developments on that railway from that time until his retirement, and from 1901 held the position of Electrical Superintendent. During that period the electrical work on the railway developed from an annual consumption of one million units to 28 times that amount. Although the heavier applications of electrical energy formed the major portion of his later work, he still retained a keen interest in railway signalling. This was to some extent inherited, for his father was a signal inspector, and it was characteristic that, when in 1898 he published a book on "Railway Block Signalling," the title page carried the dedication "To the Author's Father, an I.O.U." This book was the first in this country dealing exclusively with the principles of train signalling and apparatus for ensuring safety.

He contributed frequently to the electrical journals, and read several papers before the Institution in London and at Newcastle-on-Tyne. His masterly paper on the problems of locomotive cab-signalling will be long remembered by those who heard it delivered.

He served on the Committee of the Newcastle Local Section (now North-Eastern Centre) for several periods, and was chairman of the Section during the session 1907–8. He retired from active work on the railway at the end of 1922 after 51¾ years of service, and his death occurred when the centenary of this, the first, railway was being celebrated.

He was a shining example of a man who, having risen to a high position by his own unaided effort, was still quite unspoiled by success. It was said of him by one who was to some extent antagonistic to him in his earlier days, but who afterwards became one of his staff, "I never before had such a fine man as my chief."

F. O. H.

SIR DAVID LIONEL GOLDSMID STERN SALOMONS, BART., M.A., died on the 19th April, 1925, at the age of 73. He was the only son of Philip Salomons of Brighton, and grandson of Sir Jacob Montefiore of Sydney, New South Wales. From University College, London, he went up to Cambridge and took a 2nd class in the Natural Science Tripos in 1873. In the same year he succeeded to the baronetcy of his uncle, Sir David Salomons, the Liberal Jew who made a long fight for admission to the House of Commons, and was the first of his faith to sit there. He was called to the Bar by the Middle Temple in 1874. He was a magistrate and Deputy-Lieutenant of Kent, and was High Sheriff in 1881. In 1882 he married a daughter of the late Baron Hermann de Stern, a sister of the first Lord Michelham. Sir David was one of the oldest members of the Institution, having joined the Society of Telegraph Engineers in 1875, only four years after its formation. It was on his proposal that the Institution was formed from the old Society. He was a member of the Council and Honorary Treasurer for many years, and became a Vice-President. There is little doubt that if he had been a practising electrical engineer instead of a distinguished amateur he would have occupied the Presidential chair. He generously perpetuated his interest in and connection with the Institution by endowing the scholarship which is named after him.

He took great interest in practical electrical applications all his life, and established a laboratory and workshop at Broomhill, his seat near Tunbridge Wells, where he did a great deal of experimental work. He claimed to be the first person in this country to light his house by incandescent electric lamps—that was in 1874, when all the accessories were home-made. His book on "Electric Light Installations and the Management of Accumulators," based on his own practical experience, was one of the first on the subject. It passed through many editions. He was a director and the first chairman of the City of London Electric Lighting Co., Ltd. His interests were many and varied. He was a director of the South-Eastern Railway, and on its amalgamation with the other two lines he became a director of the Southern Railway. He was one of the pioneers of the motor-car. It is related that when he performed the opening ceremony of the electricity station at Tunbridge Wells—about 30 years ago—he arrived from Broomhill with Lady Salomons in a motor-car, which by law was not allowed to travel on a public road at more than a walking pace and was preceded by a flagman. At a very early period he made and used home-made electric carriages. He organized the first motor-car exhibition—at Tunbridge Wells—and took a prominent part in the larger exhibition held shortly afterwards at the Crystal Palace. At a meeting convened by him the Self-propelled Traffic Association was formed. As its first president he initiated and carried to success the movement to induce the Government of the day to pass a measure removing the restrictions on such traffic. He was one of the founders and an honorary member of the Automobile Club de France, and a founder and honorary president of the Aero Club de France.

He was greatly interested in early time-pieces, of which he had an important collection, including many examples of the work of Breguet. He wrote a life of Breguet which was republished in a French edition for the centenary of that famous French watchmaker. His continued interest in electrical matters as well as his kindliness is shown by his having till the last remained president of the Electrical Trades Benevolent Institution.

He leaves a widow and three daughters. His only

son, Capt. David Salomons, was drowned on service in the Hythe disaster in 1915. W. M. M.

HERBERT WATSON SULLIVAN joined the Telegraph Construction and Maintenance Co., Ltd., in 1870 and served a three years' apprenticeship with them, at the conclusion of which he joined the Eastern Telegraph Co., with whom, during a period of six years, he undertook the charge of the electrical arrangements of their Gibraltar station and assisted the late Mr. C. V. de Sauty in the first successful duplex experiments on long submarine cables. The almost continuous ill-health that so seriously handicapped Mr. Sullivan's career then made itself apparent, and he was invalided home, but with characteristic courage and determination he resumed his duties within a few months, and served with the staff afloat for two years. Rejoining the Telegraph Construction and Maintenance Co. in 1879 he assisted at many important cable-laying undertakings, including the Ireland–Newfoundland, Singapore–Batavia, Lisbon–Madeira duplicate, Suez–Aden triplicate, and the Straits of Sunda and Mozambique–Zanzibar duplicate. Subsequently he became associated with two French companies, La Compagnie Française des Cables Télégraphiques and La Société Industrielle des Téléphones, for whom he installed and organized a number of cable stations in various parts of the world. He served as electrician-in-chief and consulting engineer respectively during the manufacture and submersion of the last French Government cables between Marseilles and Tunis, and between the Australian Continent and New Caledonia. In 1897 Mr. Sullivan established himself in business in order to manufacture certain patented instruments, together with cable, testing, and telegraph signalling apparatus generally. The universal galvanometer which he invented and developed achieved instant and world-wide reputation, and the whole range of work he produced showed in a marked way the predominating characteristic of the man—that of taking infinite pains. The business steadily increased in prosperity and reputation, and in its administration Mr. Sullivan exhibited that rare combination of firmness and tact that has guided it through many difficulties and endeared him to those who have had the pleasure of working under him. The valuable assistance which he rendered to the Government in the early days of the war, mainly in the development of wireless telegraphy, laid the foundations of an extensive connection with the Home Departments and Foreign Governments, and with the expressed wish of providing for its continuance after his death, Mr. Sullivan in 1922 formed the business into a limited company. During the last few years it became clear that his health was so impaired that he should take more rest from the continuous detail work entailed by the company's ever-expanding activities, but his determination to continue was unbroken and he died, as he would have wished, in harness. He was elected an Associate of the Institution in 1878 and a Member in 1892. D. A. S.

HUGH LAWRANCE WILLIAMS received his education at Charterhouse and Trinity College, Cambridge, and from there went to Messrs. Thomas Parker, Ltd., where he was a pupil from 1896 to 1899. From 1900 to 1906 he was with Messrs. Lowdon Bros., leaving there to join the firm of J. G. White and Co. as constructional engineer. He became chief engineer to Messrs. Balfour, Beatty and Co., in 1909 on the foundation of the business, and was one of the principals of that firm from 1913, continuing in that position until his death, which occurred on the 25th July, 1925, at the age of 52. He was elected an Associate Member of the Institution in 1909 and a Member in 1918.

GEORGE MACDONALD WISE received his technical education at the Victoria Technical Institute and the Glasgow and West of Scotland Institute from 1893 to 1896. He then became a pupil in the shipbuilding firm of Wm. Denny and Brothers, Ltd., Dumbarton. He first went to sea as an engineer and afterwards joined the staff of the Bengal Iron and Steel Co. at Barrakar. In 1907 he became associated with Messrs. Tata, Bombay. Soon after Jost's Engineering Co., Ltd., electrical and mechanical engineers, Bombay, was formed, Mr. Wise became associated with it, first as assistant manager, then as manager, and finally as managing director, which office he held until his death on the 5th December, 1924. He was elected an Associate Member of the Institution in 1909 and a Member in 1922.

CHARLES HENRY WORDINGHAM, C.B.E., died on the 28th January, 1925. His friends in the Institution who had for some time taken a grave view of his illness, and the electrical world who were taken by surprise, heard with the deepest sorrow that Wordingham, a household name to all, had passed away. Born at Twickenham on the 14th April, 1866, his father being a medical man, he was educated at King's College School, and in 1882 entered the Engineering Department of King's College, London. Here he distinguished himself, being, as he always was, an indefatigable worker and throwing himself into not only the class-room and laboratory work, but also the social activities of the College. He was at one time secretary, and later president, of the King's College Engineering Society. He never lost his interest in "King's," and at the time of his death was on the council and delegacy of the College and president of the Old Students' Association.

On leaving King's College he was articled to the late Dr. John Hopkinson, F.R.S., and subsequently was with the United Telephone Co., but in 1889 he may be considered to have made his entry into the branch of the profession in which his future career was to lie, for in that year he became third engineer at the Grosvenor Gallery generating station of the London Electric Supply Corporation, in charge of the standardization department and the distribution substations. Perhaps it was here that his mind turned to standardization, a subject in which he eventually took so prominent a part.

In 1892 he joined Dr. John Hopkinson as assistant, and it was in this capacity that he was engaged on

the first lighting station of the Manchester Corporation. On the completion of the contract in 1894 he became the first City Electrical Engineer to the Manchester Corporation, a post which he held until 1901, during which time great developments took place. Before he left, his plan for a new combined tramway and lighting station with high-tension distribution was completed and was subsequently carried out by the Corporation.

In 1901 he left the Manchester Corporation and became a consulting engineer, carrying out certain Parliamentary work and work connected with company and municipal power and lighting schemes.

In 1903 he was appointed Head of the Electrical Engineering Department of the Admiralty, in which capacity he reorganized the electrical equipment of the Navy. It was no doubt his experience gained in electrical distribution on land that led him to adopt lead-covered paper-insulated cables for the principal mains on the larger ships. He introduced many entirely new features into the equipment and, no doubt, in some cases met with considerable opposition to his strong views.

Two matters outside his direct professional work were always in his mind. Standardization in the electrical world may almost be said to be his work. He was the driving force behind nearly every section of this work, and as a collateral activity was chairman of the Ship Electrical Equipment Committee of the Institution, and at the time of his death was also chairman of its Wiring Rules Committee. Another project at which he worked with great energy, arising from a need he had felt when he was with the Manchester Corporation, was a scheme for a Proving House to which appliances and material could be submitted to be tested as to their compliance with specified requirements. This scheme has not yet matured. He was a member of the Main Committee, and chairman of the Electrical Sectional Committee, of the British Engineering Standards Association, and a member of the British section of the International Electrotechnical Commission. He represented the Institution of Electrical Engineers on the General Board and Executive Committee of the National Physical Laboratory, was a member of the Council of the British Electrical Development Association, in the foundation of which the Institution co-operated, and he also represented the Institution on the Electrical Research Association, and was the first Chairman of the Council of the British Electrical and Allied Industries' Research Association, of which later he was the first President. He took a prominent part in the formation of the Incorporated Municipal Electrical Association and was its second President, serving in that capacity in 1896–97.

His connection with the Institution was a long one: he became an Associate in 1887, and a Member in 1894. He worked actively during the time he was in Manchester to strengthen the Institution in the provincial centres, and was Chairman of the Manchester Local Section, now the North-Western Centre, in 1901. He served on the Council from 1897 to 1902, from 1905 to 1908, and from 1909 to 1912; became Vice-President in 1914, was elected President in 1917 during the war period, and was re-elected President in 1918. His Presidential Address in 1917 outlined a scheme for the organization of the whole electrical profession and industry, and much that he then advocated has since been carried out. It was during this period that in the year 1918 he was created C.B.E., when he retired from the Admiralty and again became a consulting engineer, and he was still in practice at the time of his death.

He married in 1912 Emily Anne, daughter of the late Charles John West, J.P., of Queensland, and his wife and five children survive him.

His work at the Institution can be fully appreciated only by those on the Council and Committees of that body. No task was too great for the Institution he loved so well, and much of the great success and prosperity of the Institution of later years may be traced to his work. He advocated and prepared the way for the granting of the Charter by H.M. the King in 1921.

Of the man much might be written. In intellectual qualities he won through by sheer hard work rather than by brilliance; he studied every side of a question, and so prepared for himself the elements of every problem, and then logically developed the result that would follow, thus giving himself that clearness of prevision and foresight which he showed to such purpose. Once having made up his own mind he became an enthusiast to convert every opponent, every waverer. He found it difficult to see other people's point of view —a strength and yet a weakness. Those who worked with him in committee know how much time he spent in trying—often successfully—to convert a whole committee to his view. He occupied his mind little with abstruse questions of science or philosophy; essentially simple in his method of life, intensely practical in organization and management, satisfied with the religious faith of his forefathers, an ardent friend, a helper of younger men, he endeared himself to all. Many will remember his tender affection for his mother, who for many years accompanied him at the functions which he attended. About two years before his death he had a serious breakdown, but he was ill before this happened. The first sign to his friends who knew him well was when, at a dinner of an Association, he made a speech in which he practically despaired of the completion of the work of the Wiring Rules Committee, the first time he had ever been known to waver on a matter upon which he had set his heart. Possibly the work he undertook during the war had already overtaxed him. After the recovery from this breakdown he returned to his accustomed tasks, but he had lost power and was evidently working under difficulties; his holiday did not refresh him, a second breakdown followed, a long illness borne bravely and hopefully ended more suddenly than anyone expected, leaving to the Institution and his friends a memory that will long shine as an example and an inspiration.
